Preface

The enclosed papers were prepared for the International Symposium and Workshop on the Application of Mathematical Models in Hydrology and Water Resources Systems held in Bratislava, Czechoslovakia, on 8-13 September 1975.

The papers are being published in this format because the distribution of the original reports was extremely limited. There is a need for this information to be available to potential users of the catchment model of the National Weather Service River Forecast System. This system comprises a number of hydrologic models which are being incorporated into an operational river forecasting program. The system is being implemented by the Hydrologic Services Division and the Hydrologic Research Laboratory of the Office of Hydrology.

CATCHMENT MODELING WITH THE UNITED STATES NATIONAL WEATHER SERVICE
RIVER FORECAST SYSTEM

Eugene L. Peck
Director, Hydrologic Research Laboratory
National Weather Service, NOAA, Silver Spring, Md., U.S.A.

ABSTRACT. The system (NWSRFS) of conceptual hydrologic models and other procedures, used in the operational river forecasting program of the United States National Weather Service, is briefly described. Complete information on the system as it existed in 1972 was published. However, since then the operational system has been expanded and revised frequently. Information on new procedures will be published in the technical literature.

A major revision has been made in the soil moisture accounting for the catchment model. The components for soil moisture accounting of the Sacramento Model have replaced those of the modified Stanford Model as used in the original system. The conceptual features and characteristics of the Sacramento Model are discussed. The demonstration in the workshop of this symposium will be limited to the catchment model.

- A - Procedures for archiving, retrieving and processing the types of data needed to apply the system.
- B - Methods needed to calibrate the various hydrologic techniques, that is, to evaluate the parameters to apply a hydrologic or hydraulic model to a specific location.
- C - Computer programs necessary to execute the hydrologic techniques and support procedures described above, in both the development and operational modes.

The system was begun in 1971, along the lines described above and published as NOAA Technical Memorandum NWS HYDRO-14, National Weather Service River Forecast System Forecast Procedures, as originally published, the system included a modification of the Stanford Watershed Model IV, based on the work of Stanford and Linley (1966).

The nature and concept of the system are such that it may be expected to be constantly changing. New hydrologic techniques become available from time to time and, if they are judged to be superior to those in the system, substitutions are made. Changes and improvements in the needs of forecast users

INTRODUCTION

In 1971, the United States National Weather Service decided to develop and publish the National Weather Service River Forecast System (NWSRFS) (NOAA, 1972). This system is a comprehensive collection of the latest hydrologic techniques and includes the basic hydrologic techniques needed by the NWS River Forecast Centers to perform their operational functions. Each technique has been developed and/or evaluated by the Hydrologic Research Laboratory of the National Weather Service. These hydrologic techniques include, but are not necessarily limited to, the following:

1. A catchment model which, through the use of soil moisture accounting formulations and the mathematical modeling of flow through and above the soil mantle and within the channel, convert moisture input (rainfall or snow-melt) to a hydrograph of channel discharge at the outlet of the catchment.
2. A mathematical model of the accumulation and ablation of snow.
3. Channel routing models which model the translation and attenuation of a flood wave as it moves between two points in a channel.
4. Techniques for modeling the areal distribution of precipitation, to be used for computing the moisture input to a catchment on the basis of point values measured at rain gauges.

In addition to the hydrologic techniques, the system includes three other categories of material.

- A - Procedures for archiving, retrieving and processing the types of data needed to apply the system.
- B - Methods needed to calibrate the various hydrologic techniques, that is, to evaluate the parameters to apply a hydrologic or hydraulic model to a specific location.
- C - Computer programs necessary to execute the hydrologic techniques and support procedures described above, in both the development and operational modes.

The system was begun in 1971, along the lines described above and published as NOAA Technical Memorandum NWS HYDRO-14, National Weather Service River Forecast System Forecast Procedures. As originally published, the system included a modification of the Stanford Watershed Model IV, based on the work of Crawford and Linsley (1966).

The nature and concept of the system are such that it may be expected to be constantly changing. New hydrologic techniques become available from time to time and, if they are judged to be superior to those in the system, substitutions are made. Changes and increases in the needs of forecast users

may present a need for new hydrologic products and the techniques needed to produce them. Advances in computing equipment and/or changes in the equipment available to the service also require revisions to the computer programs.

NWSRFS MODIFICATIONS

Additional procedures are being included in the NWSRFS to expand the flexibility of the system. A major change has been made in the basic soil moisture accounting. The soil moisture accounting system of the catchment model developed in the NWS Sacramento, California River Forecast Center by Burnash, et al. (1973), is now included in the system. The method employed includes a minor modification of the temporal distribution function from that described in the original Sacramento model.

SOIL MOISTURE MODEL

The soil moisture models that have been used in NWSRFS have been conceptual in design. This resulted from a firm belief that a number of benefits accrue from a strong physical base. Some of these are:

1. The performance of the model in simulating the past is the only available objective measure of the model's ability to predict the future. It is, however, an indirect and imperfect measure. Where accurate simulation of the past has been attained, a high degree of conceptuality enhances the probability of adequately predicting future events. This is especially true in the case of extreme events involving values of variables not experienced in historical data, or, experienced values of the variables but in unexperienced combinations.
2. Models of this type are necessarily complex and involve a large number of parameters. The evaluation of parameter values for a specific catchment is a very serious problem, always involving a number of successive approximations. The chances of obtaining something close to the true values of the parameters are increased if the first approximation is reasonable. If the parameters have real physical meaning, good first approximations of their values may be inferred from streamflow records and various observable basin characteristics.
3. Parameters based on conceptual considerations can sometimes be subjectively altered to reflect changes made or to be made to the physical characteristics of the catchment thereby mitigating the need to wait for a new data base to be developed.
4. A conceptual model can be applied to problems other than discharge prediction. Some examples are, movement of pollutants through the soil mantle, water temperature prediction and determination, and prediction of soil moisture levels for agricultural purposes.

5. A model that is conceptually based provides a more effective structure for future modification and research.

The demonstration in the workshop associated with this symposium will be limited to the portions of the system pertaining to a single catchment area. There would not be adequate time to demonstrate all of the flexibility of NWSRFS. Therefore, only the significant hydrologic concepts of the catchment (Sacramento) model and minor modifications as made for its adoption in NWSRFS are discussed.

Model Classification. The Sacramento soil moisture model is of the deterministic, lumped input, lumped parameter type. The originators, while fully cognizant of the variability of physical characteristics and hence parameters within a catchment, did not feel that any existing method of modeling this variation, or any they could devise at that time, was adequate or realistic. They therefore opted to design their model as a lumped parameter technique. They did, however, include a "variable impervious area" and an incrementation of lower zone free water when tension water is not completely satisfied. These two features give the model some of the characteristics of a probability distributed parameter model.

Model Structure. Two zones, upper and lower, are defined. The upper zone represents the upper soil layer and interception storage while the lower zone represents the bulk of the soil moisture and longer groundwater storage.

Moisture Storage. Each zone is thought of as storing moisture in two forms, "tension water" and "free water." Tension water is that which is closely bound to the soil particles in contrast to the water that is free to move. For any zone, the maximum amounts of tension water and of free water which the zone can hold are specified as model parameters. The amount of water in each of these storages at any time is a model variable. The basic storage mechanics are that moisture entering a zone is stored as tension water until the tension capacity is filled. In the lower zone, however, a portion of the water entering that zone may be diverted to free water storage before tension water is filled. Once tension water capacities are filled, then additional water will be stored as free water. Depletion of free water occurs vertically as percolation, horizontally as channel inflow and non-channel groundwater outflow or as evapotranspiration. Tension water is depleted only as evapotranspiration.

Channel Flow from Groundwater. In order for a continuous model to accurately simulate extended periods of fair weather flow, it must have a rather complex groundwater flow withdrawal function. In this model, this is accomplished by defining two lower zone free water storages: primary, which is slow draining and longer lasting, and supplementary, which is faster draining. The outflow from each of these is, in each computational time period, the product of the contents and a constant withdrawal parameter. The two parameters (primary and supplementary) are not equal to each other. While the depletion functions are simple, the total groundwater outflow is governed by these functions acting in combination with some rather involved mechanics which apportion inflow to the lower zone between the two free water storages, and balance tension and free water storages. The originators of the model

believe the concept of two separate groundwater components to have some basis in fact and have had a degree of success in identifying them from observed streamflow records.

Percolation. The flow of water from the upper zone to the lower zone is expressed by a formula considered to be the "heart" of the model. In this formula, a percolation rate "PBASE" is defined as the maximum lower zone flow-through rate. This is numerically equal to the outflow from the lower zone under saturated conditions.

Under conditions of unlimited moisture availability in the upper zone, the actual percolation rate may vary between "PBASE" when the lower zone is full, and a maximum value which would occur if the lower zone were empty. This maximum rate is defined by a percolation parameter, "ZPERC," such that the maximum rate is equal to the product of "PBASE" and "1+ZPERC."

The variation of percolation rate between the minimum and maximum values thus defined occurs as a function of the lower zone deficiency ratio. This ratio (DEFR) is simply the difference between lower zone contents and capacity divided by the capacity. The ratio may vary from zero (lower zone full) to unity (lower zone empty). In its computation, both tension and free water are considered. In order to permit the effect of the deficiency ratio to be non-linear and to vary among catchments, a parameter "REXP," which is dependent upon soil type, is applied to the ratio as an exponent. Thus, the actual percolation rate under conditions of unlimited moisture availability in the upper zone is given by:

$$\text{RATE} = \text{PBASE} (1 + \text{ZPERC} * \text{DEFR}^{\text{REXP}})$$

where:

RATE is the percolation rate as defined above.

DEFR is the lower zone deficiency ratio.

The true percolation rate is equal to the product of "RATE" and the "upper zone driving force," which is the ratio of upper zone free water contents to upper zone free water capacity. Thus, the percolation will be zero if upper zone free water is empty and equal to "RATE" if the upper zone is full.

The formula involves eight model parameters. Two of them, ZPERC and REXP, appear only in this formula. The remaining six serve their primary purpose in other parts of the model. Four model variables, related to storages in both zones, also appear. The formula interacts with other model components in such a way that it controls the movement of water in all parts of the soil profile, both above and below the percolation interface and is, in turn, controlled by the movement in all parts of the profile.

Variable Impervious Area. A portion of the water entering the basin is assumed to be deposited on impervious areas directly connected or adjacent to the channel system and thus becomes channel flow. This portion is defined by two parameters representing its minimum and maximum values. The actual area

used in the computation varies between these limits as a function of the amount of water in storage.

Flow Components. The model recognizes and generates five components of flow:

1. Direct runoff, resulting from moisture input being applied to the variable impervious area.
2. Surface runoff. When moisture input is supplied at a rate faster than it can enter the upper zone, the excess appears as surface runoff.
3. Interflow, lateral drainage from upper zone free water.
4. Supplementary base flow, lateral drainage from lower zone supplementary free water.
5. Primary base flow, lateral drainage from lower zone primary free water.

Evapotranspiration. Evapotranspiration rates in the Sacramento model may be estimated from meteorological variables or from pan observations. Either day-by-day or long-term values may be used to derive the demand curve. The catchment evapotranspiration - demand curve is a product of the computed evaporation index and a seasonal adjustment curve. The seasonal adjustment curve reflects the state of the vegetation. The moisture accounting within the model applies the evapotranspiration loss, directly or indirectly, to the various storages and/or to the channel. The amount taken from each location in the model is determined by a hierarchy of priorities and is limited by the availability of the moisture as well as by the computed demand.

Computational Technique. The movement of moisture through the soil mantle is a continuous process. The rate of flow at various points varies with the rate of moisture supply and with the contents of various storages. This process is modeled by a quasi-linear, open form computation. A single time step computation of the drainage and percolation loop involves the implicit assumption that the movement of moisture during the time step is defined by the conditions at the beginning of the time step. Since this assumption is not valid, the resultant approximation can be made acceptable only by the use of a short time step. In the model, the length of the step is volume dependent. That is, it is selected in such a way that no more than 5 mm of water may be involved in any single execution of the computational loop. The 5 mm limit is arbitrary. It was selected by the originators as being small enough to logically fulfill its function, and not so small as to cause excessively long execution times on the computer (IBM 1130) which was used to develop the model. Sensitivity tests to determine the optimal size of this limit should have a dependency upon soil type. The current limit represents a compromise to eliminate the need for an additional parameter.

Parameters. The soil moisture accounting portion of the Sacramento model, exclusive of the evapotranspiration demand curve, involves seventeen parameters. The demand curve can be defined by a series of ordinates, twelve in number, or by a formula involving five parameters. The temporal distribution function, which converts runoff volumes to a discharge hydrograph, involves a unit hydrograph, and, in some applications, a channel routing function.

The original Sacramento model applied the unit hydrograph to only the upper three components of flow. The two lower zone components were added to the channel flow in the time period in which they were released from the lower zone. In the NWSRFS version, the unit hydrograph is applied to the sum of all five components.

The application of the model in the NWSRFS involves moisture input in 6-hour time periods, and computed 6-hour runoff volumes. The short, repetitive computational time step described above is a subdivision of the 6-hour period and has mathematical significance only. The computations are accumulated over a 6-hour period and applied to a unit hydrograph function representing a 6-hour duration event.

Calibration. A very difficult problem which always accompanies the use of a hydrologic model is that of calibration or "parameter optimization." A model is obviously useless if its parameters cannot be evaluated. Yet, the determination of the optimal values of fifteen to twenty interrelated parameters is a formidable task. The National Weather Service has used a combination of manual and automatic optimization techniques. The term "manual" refers here to a procedure in which subjective adjustments to various parameters are made on the basis of specific characteristics of the output of previous computer runs. Automatic techniques are those in which the computer itself adjusts parameters in a semi-random manner, based on changes in the value of a single numerical error function. The method used is an application of the "Pattern Search" technique described by Monro (1971).

There is no doubt that a good set of parameters can be obtained using only manual methods. However, the procedure is time consuming in terms of man-hours and requires a degree of interplay with the computer often not available from larger systems. In addition, the hydrologist performing the optimization must possess a considerable degree of skill acquired through experience with the model. Automatic methods, on the other hand, are fast and simple to use. Besides being expensive from a computer usage standpoint, they have some inherent disadvantages. Some of these are: complete dependency on one error function, failure to attain an optimal solution due to non-convexity of the response surface in the vicinity of the starting point, and failure to recognize the effect of perturbing a group of parameters simultaneously. At its worst, such a procedure can degenerate into pure curve fitting and produce a set of parameters which fit the calibration data reasonably well, but which are hydrologically unrealistic.

Experience in fitting the model to a large number of catchments under operational conditions indicates that the procedure should be one involving both manual and automatic fitting where the strong points of each compensate the weak points of the other. Generally, much more is achieved by fitting manually first, then using the automatic optimizer after a reasonable fit has been obtained.

Data requirements for the model are somewhat greater than for simpler "event" type models, since the model utilizes a continuous record rather than a fragmentary one covering selected periods.

The length of the data base required for adequate calibration depends on a number of factors including the hydro-climatic characteristics of the catchment and the amount of hydrologic activity during the period in question. Typically, however, it runs 8 to 10 years.

COMPLETE NWSRFS

The National Weather Service River Forecast System is continually being updated and expanded. It contains many models and procedures including the catchment model. Routing and data handling and processing procedures required to adapt the system to a particular river basin are also included in the complete NWSRFS system.

The modular form of the NWSRFS permits the incorporation of additions and improvements with a minimum of programming effort. A snow accumulation and ablation model (Anderson 1973) has been added to the original system. Dynamic (implicit) routing techniques for use on major rivers where serious backwater problems are encountered due to interconnected river systems or tidal effects (Fread 1973) are being incorporated into the system.

It is not planned to publish the entire revised NWSRFS since it is an operational system and subject to frequent modifications. The complete system will be available only on the NOAA's central computer system for use by the NWS River Forecast Centers. However, information on new and revised techniques will continue to be published in the literature.

CALIBRATION OF NATIONAL WEATHER SERVICE RIVER FORECAST SYSTEM:
INITIALIZING PARAMETERS FOR THE CATCHMENT MODEL

Eugene L. Peck
Director, Hydrologic Research Laboratory
National Weather Service, NOAA, Silver Spring, Md., U.S.A.

ABSTRACT. Use of the catchment model in the National Weather Service River Forecast System (NWSRFS) requires the determination of 16 model parameters. The calibration process is greatly enhanced if rational initial estimates of model parameters can be found. Techniques are developed to derive initial parameter estimates directly from the hydrometeorological data base of a catchment. The techniques utilize catchment maps, precipitation records, and streamflow records to estimate the magnitudes of soil moisture storage components and appropriate drainage coefficients. Step by step demonstrations of the estimation procedure are included. As an example, parameter estimates are obtained for simulation of the South Yamhill River near Whiteson, Oregon.

REQUIREMENTS FOR HYDROGRAPH SIMULATION

Simulation required to test the validity of the soil moisture parameters involves three other elements. These are:
1. Mean areal precipitation (MAP). This includes all the techniques and procedures necessary to arrive at basinwide estimates of mean areal precipitation for use by the soil moisture accounting portion of NWSRFS. Included are methods for estimating missing precipitation amounts, distributing estimated or accumulated precipitation, and adjusting precipitation data for orographic and/or other effects. In basins in which snow occurs, input to the catchment program consists of the liquid water reaching the soil mantle from a combination of rainfall and snowmelt. The snowmelt may be either estimated or computed from the NWSRFS snow accumulation and ablation model (Anderson 1973).

INITIALIZING PARAMETERS FOR THE CATCHMENT MODEL

Eugene J. Peck

Director, Hydrologic Research Laboratory

National Weather Service, Spring, No. 1, U.S.A.

INTRODUCTION

The soil moisture accounting program of the catchment model developed in the National Weather Service (NWS) Sacramento, California, River Forecast Center by Burnash, et al. (1973), is presently used in the National Weather Service River Forecast System (NWSRFS) (NOAA 1972). A general description of the model is given in the companion paper prepared for this workshop (Peck 1975). Figure 1 is a flow diagram illustrating the various paths water takes in the model. A listing of the NWSRFS subroutine for this model appears in appendix D.

Calibration of the catchment model requires determination of values for 16 parameters associated with soil moisture accounting. This section describes methods for determining initial parameter values. All the parameters are depicted in figure 1.

REQUIREMENTS FOR HYDROGRAPH SIMULATION

Simulation required to test the validity of the soil moisture parameters involves three other elements. These are:

1. Mean Areal Precipitation (MAP). This includes all the techniques and procedures necessary to arrive at basinwide estimates of mean areal precipitation for use by the soil moisture accounting portion of NWSRFS. Included are methods for estimating missing precipitation amounts, distributing estimated or accumulated precipitation, and adjusting precipitation data for orographic and/or other effects. In basins in which snow occurs, input to the catchment program consists of the liquid water reaching the soil mantle from a combination of rainfall and snowmelt. The snowmelt may be either estimated or computed from the NWSRFS snow accumulation and ablation model (Anderson 1973).

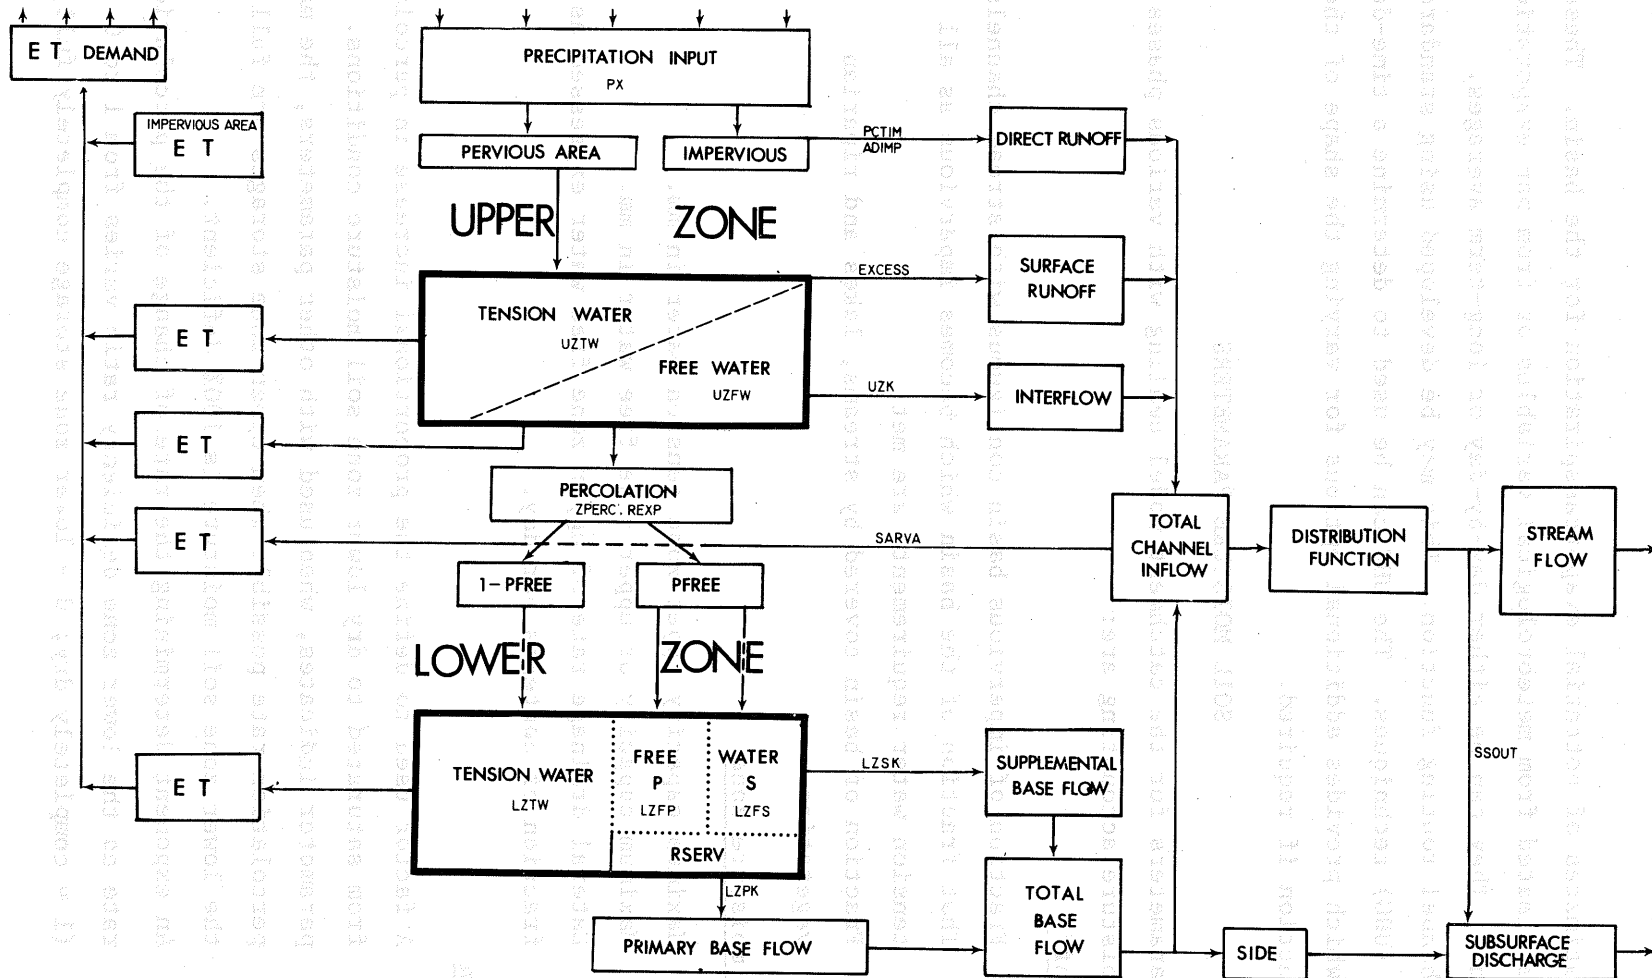

Figure 1.--NWSRFS catchment model (Sacramento),

2. Estimates of potential evapotranspiration for the basin. These values can be estimated from meteorological variables or from pan evaporation observations. They can be either day-by-day or long-term averages.

3. Channel routing function. This may be developed using standard unit hydrograph (UHG) techniques. The UHG can be used to determine a time-delay histogram which provides additional options for varying the shape of the routing function if required.

SOIL MOISTURE PARAMETERS

The parameters for the catchment model dealing with various phases of the soil moisture accounting are:

Direct runoff

- PCTIM Fraction of impervious basin contiguous with stream channels.
 ADIMP That fraction of the basin which becomes impervious as all tension water requirements are met.
 SARVA Fraction of basin covered by streams, lakes and riparian vegetation.

Upper soil moisture zone

- UZTWM Maximum capacity upper zone tension water in mm.
 USFWM Maximum capacity of upper zone free water in mm.
 UZK Lateral drainage rate of upper zone free water expressed as a fraction of contents per day.

Percolation

- ZPERC A factor used to define the proportional increase in percolation from saturated to dry lower zone soil moisture conditions. This parameter indicates, when used with other parameters, the maximum percolation rate possible when upper zone storages are full and the lower zone soil moisture is 100% deficient.
 REXP An exponent determining the rate of change of the percolation rate as the lower zone deficiency ratio varies from 1 to 0 (1 = completely dry; 0 = lower zone storage completely full).

Lower zone

- LZTWM Maximum capacity of lower zone tension water in mm.
- LZFSM Maximum capacity of lower zone supplemental free water storage in mm.
- LZSK Lateral drainage rate of lower zone supplemental free water expressed as a fraction of contents per day.
- LZFPM Maximum capacity of lower zone primary free water storage in mm.
- LZPK Lateral drainage rate of lower zone primary free water expressed as a fraction of contents per day.
- PFREE The percentage of percolation water which directly enters the lower zone free water without a prior claim by lower zone tension water.
- RSERV Fraction of lower zone free water not available for transpiration purposes (incapable of resupplying lower zone tension water).
- SIDE The ratio of unobserved to observed baseflow.
- SSOUT A fixed rate of discharge lost from the total channel flow.

PARAMETER GROUPINGS

If the conceptual model is realistic for the basin, such that parameters have physical meaning, good first approximations for some of the parameters may be inferred from streamflow records, precipitation records, and other basin characteristics. The chances of obtaining the most representative set of parameters are increased with successive approximations if the first approximations are reasonable.

The soil moisture model parameters may be grouped according to the methods for obtaining first approximations. The parameters and their associated classifications are:

1. Parameters readily computed from observed hydrograph and precipitation

LZFPM	LZSK
LZPK	PCTIM
LZFSM	

2. Parameters more difficult to estimate from observed hydrograph

LZTWM	SSOUT
UZTWM	UZFWM*
UZK	PFREE*

*Relative size only.

3. Parameters estimated from maps of water area

SARVA

4. Relative values could possibly be estimated for the following parameters from soil percolation characteristics. However, the best first estimate is to use values from similar nearby basins that have been previously simulated.

ZPERC

REXP

5. Nominal starting values used

SIDE

ADIMP

RSERV

INITIAL PARAMETER DETERMINATION

The South Yamhill River near Whiteson, Oregon, U.S.A., has been selected for use as an example for this workshop. Appendix A contains semilogarithmic plots of the observed hydrograph for this river for the water years 1963 (Oct. 1962 to Sept. 1963) and 1965 (Oct. 1964 to Sept. 1965). These plots contain sufficient variations in observed flows for computing those initial soil moisture values determined from observed hydrographs.

Hypothetical examples are discussed in this section to guide the workshop participant in selecting initial parameters for the South Yamhill Basin. For comparison purposes, actual examples of determination of initial parameter values for the South Yamhill Basin will be demonstrated in appendix B. The South Yamhill Basin was selected for an example since it has a large variation in hydrologic flow conditions, which makes it ideal for demonstrating determination of initial parameters.

Semilogarithmic hydrograph plots have commonly been used to separate hydrographs into principal flow components of surface runoff, interflow, and groundwater recession as shown in figure 2 (Linsley, Kohler, and Paulhus

Figure 2.--Semilogarithmic plotting of a hydrograph, showing method of recession analysis.

1975). The characteristics of the hydrograph recession may be used to obtain initial values for the maximum capacities and depletion coefficients for the lower zone free water storages (LZFPM, LZFSM, LZPK, and LZSK).

If a groundwater recession continues for some time, the recession is characterized by two distinct slopes, with a much flatter recession occurring after a prolonged dry period. The developers of the soil moisture model believe the base flow can be modeled with two slopes representing two separate sources of base flow with separate exponential decaying functions. For the model being used, these are the supplemental and primary free water storages of the lower zone. Analyses of the recession provide methods for estimating the depletion rates and storages for the two zones. This is accomplished for each free water storage as follows:

Primary (LZPK and LZFPM)

Select a period when the recession is the flattest (least decay with time) with a minimum of precipitation and calculate a slope during this period.

Example:

Primary flow on August 1: 0.42 mm (QP_2)

Primary flow on June 1: 0.50 mm (QP_1)

Primary daily recession rate (K_p) = $(QP_2/QP_1)^{1/t}$

where: t is time in days

$$K_1 = (0.42/0.50)^{1/61} = 0.997$$

$$LZPK = 1 - K = 0.003$$

A value for the maximum free primary water storage may be obtained by dividing the maximum discharge under only primary flow conditions by the daily depletion rate (LZPK). This calculation should be based on the largest value of primary flow which can be observed or estimated from the hydrograph trace.

$$LZFPM = QP_1/LZPK = 0.42/0.003 = 140 \text{ mm}$$

Supplemental (LZSK and LZFSM)

Computations similar to those used for the primary storage values are used for the supplemental values. In this case, estimates of the primary baseflow contribution to the observed flow must be subtracted before the slope representing the supplemental baseflow is computed.

Example:

Period selected: March 1 to April 9

Discharge	March 1	April 9
Observed	8.10 mm	1.68 mm
Estimated primary	<u>0.10 mm</u>	<u>0.08 mm</u>
Estimated supplemental	8.00 mm	1.60 mm

Supplemental daily recession rate (K_s) = $(1.60/8.00)^{1/40} = 0.960$

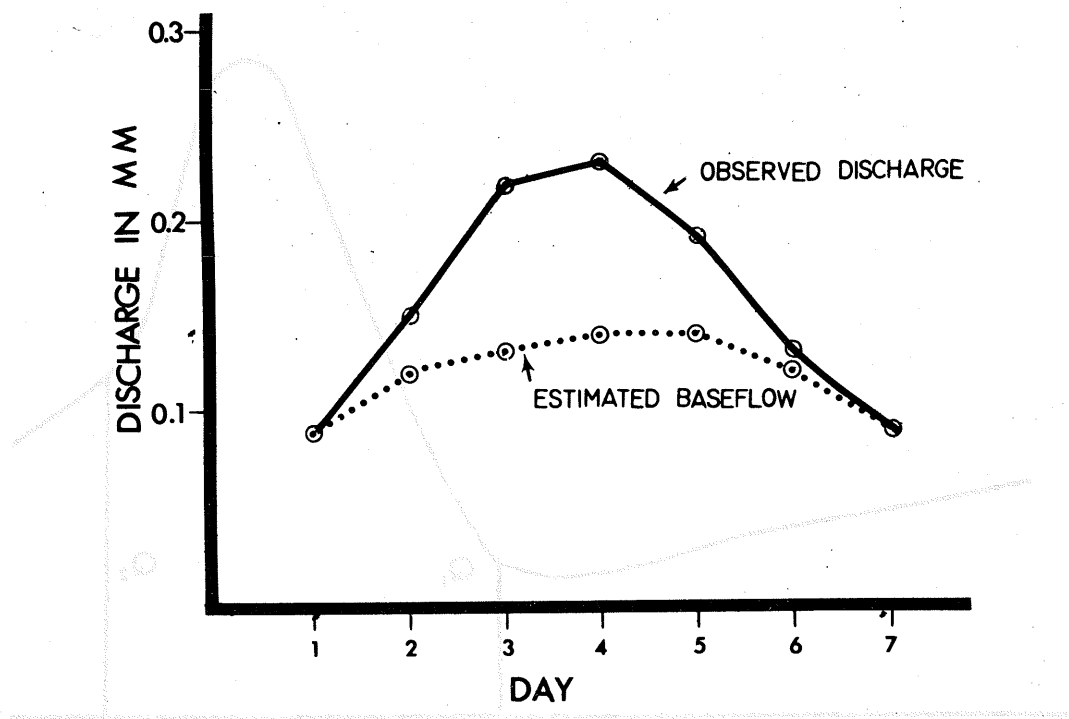

$$LZSK = 1 - K_s = 1 - 0.960 = 0.040$$

and

$$LZFSM = 8.00/0.040 = 200 \text{ mm}$$

Percent Impervious (PCTIM)

A small rise on the hydrograph during an extended dry period may be used to compute a value for PCTIM. This is calculated as shown in figure 3.

Day	Basin rain (mm)	Observed discharge (mm)	Estimated baseflow (mm)	Estimated direct R.O. (mm)
1	0.0	0.09	0.09	0.00
2	30.0	.15	.12	.03
3	19.0	.22	.13	.09
4	0.0	.23	.14	.09
5	0.0	.19	.14	.05
6	0.0	.13	.12	.01
7	0.0	0.09	0.09	.00
	49.0			0.27

$$\text{PCTIM estimate} = \frac{\sum \text{Direct R.O.}}{\sum \text{Rain}} = \frac{0.27}{49} = 0.0055$$

Figure 3.-- Calculation of PCTIM

Lower Zone Tension Water Maximum (LZTWM)

Select a period following an extended dry period, as indicated on figure 4, where the discharges Q_1 and Q_2 represent only baseflow. A time t_1 should be selected immediately prior to the occurrence of direct and/or surface runoff and time t_2 immediately following a period of interflow.

Figure 4.-- Hydrograph for determination of LZTWM

The discharges Q_1 at t_1 and Q_2 at t_2 can be separated into the supplemental and primary baseflow components by projecting primary baseflow backwards from later periods.

$$\text{At } t_1: Q_1 = QS_1 + QP_1 \quad \text{and} \quad \text{at } t_2: Q_2 = QS_2 + QP_2$$

Primary and supplemental free water storages (LZFPC and LZFSK) for each of the two times are computed by dividing the storages by the appropriate drainage rates.

$$\text{LZFPC} = \text{QP}/\text{LZPK}$$

$$\text{LZFSK} = \text{QS}/\text{LZSK}$$

Assuming that UZTW is full and UZFWC is empty at times t_1 and t_2 , the water balance for the period may be expressed as:

$$P_x - R\emptyset - PE - \Delta\text{LZFSK} - \Delta\text{LZFPC} - \Delta\text{LZTWC} = 0$$

where: P_x is precipitation during the storm in mm.

$R\emptyset$ is the total runoff in mm.

PE is the evaporation from the basin in mm (for most wet periods, this would be small and can be neglected).

Δ LZTWC is the change in the lower zone tension water.

All values except Δ LZTWC are measured or estimated. The Δ LZTWC represents the increase in the LZTW during the time interval and not necessarily LZTW being completely filled. This is an indication of the lower limit of LZTWM. Since the LZTW would probably not have been entirely empty prior to the storm, a small percentage (10% to 20%) should be added to Δ LZTWC for small storages of LZTW, to arrive at an estimate for LZTWM. For large lower zone tension storage the percentage to be added should be larger (10-40%). For cases where these ideal conditions following an extended dry period cannot be found then a water balance for a larger period of 3 to 4 months can be used to compute LZTWM.

Upper Zone Tension Water Maximum (UZTWM)

An estimate of UZTWM from the hydrograph is feasible. All periods of rain following a dry period should be checked to determine the amount of precipitation the pervious area can hold without surface runoff occurring. Where the precipitation is associated with only the one period, the entire amount can be used in making the estimate. If precipitation occurred over several days, it is more difficult to calculate the value since evaporation losses during the period must also be considered.

For the Yamhill River near Whiteson, the following were observed to have occurred.

Approximate date

Remarks

17 Oct. 1958

3-day storm of 76 mm with surface runoff.
Low UZTW prior to storm.

4 Sept. 1959

3-day storm of 42 mm overflowed UZTW.
Condition of UZTW at start of storm not certain.

23 Oct. 1960

6-day storm of 76 mm. Produced some overflow of UZTW.

23 Aug. 1963

3-day storm of 23 mm and a 5-day storm of 31 mm.
Produced no overflow of UZTW.

13 Sept. 1973

4-day storm of 35 mm with no overflow of UZTW.

Upper Zone Free Water Maximum (UZFWM) and Drainage Rate (UZK)

The UZFWM cannot be obtained directly from the interflow recession as can be done for the lower zone storages since it does not produce a straight line on semi-log hydrographs. The upper zone free water storage must satisfy percolation and evaporation demand requirements before any water is discharged to the channel. Thus, it is not a simple depletion as for the lower zone free water storages.

Although UZK cannot be obtained directly from analysis of the hydrograph, it is roughly related to the amount of time that interflow occurs following a period with major direct and surface runoff. The longer the period of interflow, the smaller the value of UZK. If we assume that interflow becomes insignificant when its contribution reduces to about 10% of what it is at maximum rate, then the following simple relation can be used to compute a value for UZK:

$$(1 - \text{UZK})^N = 0.10$$

where: N is the average number of days that interflow is observed,

A value of UZFWM can be determined using the UZK computed above and the discharge, corrected for supplemental and primary baseflow, at the time of the highest interflow with u^+ surface water contribution. It must be recognized that this is a rather rough estimate. The general range for UZFWM has been found to be from 6 to 85 mm with an average of about 25 mm.

Percolation Water Percentage (PFREE)

An estimate of the relative importance of PFREE can be determined from investigating storms following long dry spells that do produce runoff (UZTW completely filled). If the hydrograph returns to approximately the same baseflow as before (indicating little or no addition to the lower zone free water storages), then PFREE is of little significance and has a very small value ranging from 0 to 0.2. If there is a significant increase in baseflow following this type of storm, then PFREE can have a value as high as 0.5. The nominal value for PFREE is 0.3.

Sub-surface Outflow Along Stream Channel (SSOUT)

It is recommended that the value of zero be used. A value for SSOUT other than zero can be applied only if the Q log plot requires a constant

addition to the baseflow in order to achieve a valid recession characteristic.

Fraction of Basin Covered by Streams, Etc. (SARVA)

This factor is determined directly from maps showing water and riparian vegetation areas. SARVA can also be inferred from changes in baseflow associated with changes in ET.

Percolation Parameters (ZPERC and REXP)

An understanding of the important role played by the percolation parameters is essential to understanding the model and gaining an ability to properly fit the model. Figure 5 demonstrates the part played by the parameters in determining the maximum rate of percolation in relation to the lower zone soil moisture deficiency (DEFB). This curve represents the rate if the upper zone free water is full.

If the lower zone free water storages are full (and the upper zone free water is also at its maximum), then the rate of percolation is equal to PBASE, which is defined by:

$$PBASE = (LZFPM * LZPK + LZFSM * LZSK)$$

This is the maximum outflow that can occur from the lower zones and under steady conditions would represent the percolation to replace the amount removed from the lower zone free water storages as baseflow. As the lower zone soil moisture becomes deficient, the percolation rate increases. When the lower free water storages are completely dry (100% deficient), the percolation rate (assuming UZFW full) occurs at its maximum rate. This is equal to:

$$\text{Maximum percolation rate} = (1 + ZPERC) * PBASE$$

The shape of the percolation curve is determined by the parameter REXP as shown in figure 5.

Initial values of ZPERC must be estimated using as a guideline some evaluation of the possible maximum percolation rate that would be expected for the basin when the upper zone free water storage is full. The ability to estimate this value would increase as additional basins in an area are fitted. With no other means of estimating REXP, a nominal starting value of 1.80 is suggested.

Once an initial simulation is made, the four parameters controlling the

Figure 5.--Percolation representation.

percolation curve are very important for improving the simulation fit. For example, if following an extended dry period the simulated runoff is much less than observed, the percolation curve may be too high for large deficiencies in lower zone storages. Similar analyses of simulated versus observed runoff for periods when the lower zone moisture deficiency would be small will indicate if the curve should be raised or lowered for these conditions. The raising and lowering of the curve can be accomplished by changing ZPERC and/or the value of PBASE. PBASE is related to the maximum values for the lower zone free water storages (LZFSM and LZFPM). The relative values of the supplemental and primary storages are important for the division of the free water contribution to the recession. However, the total value of the storages is primarily important in positioning the percolation curve and may be changed for this purpose. Thus, you should not change the value of ZPERC without considering the necessity to also alter the total capacities of the lower zone free water. The value of REXP allows flexibility in the change in slope over the different values of the lower zone soil moisture deficiency. The fitting of the percolation curve to insure proper initiation of runoff under various lower soil moisture conditions is generally the most important fitting requirement after the first simulation if the volume of runoff is reasonable.

Parameters Requiring Nominal Starting Values (SIDE, ADIMP, and RSERV)

Initial value for SIDE is zero. Where it is known from geological or hydrological studies that considerable groundwater bypassed the surface channel, a value other than zero should be used.

The initial value for RSERV is 0.30 and this parameter is generally not optimized.

The additional area of the basin which becomes impervious as all tension water requirements are met (ADIMP) is generally given a nominal starting value of 0.01. Recent investigations suggest that remote sensing techniques using radiation measurements (infrared) can define areas as are indicated by ADIMP. Such measurements may be a means of providing future input for this parameter.

SIMULATION FOR SOUTH YAMHILL RIVER

Copies of the worksheets for determination of initial parameters for the South Yamhill River near Whiteson, Oregon, are shown in appendix B. These

may be used to compare with those obtained in the workshop. Appendix C contains the copies of the following printouts of the initial simulation.

1. Input parameters and other initializing entries.
2. Summation sheet of the statistical summary for the 5-year simulation (Oct. 1962-Sept. 1967).
3. Sample of yearly summary showing soil moisture accounting volumes for each month and listing of soil moisture variables at the end of each month.
4. Semilogarithmic hydrographs for all 5 years of observed and simulated discharges with daily numerical values of the observed discharges, simulated discharges, and liquid water reaching the soil mantle from a combination of rainfall and/or snowmelt (rain + melt).

ACKNOWLEDGMENTS

Special thanks are extended to Eric Anderson and Robert Burnash for the technical advice they provided and to the many members of the Hydrologic Research Laboratory who assisted in preparing the material.

SEMI-LOG MEAN DAILY FLOW PLOT(MM) SOUTH YAMHILL NR WHI WATER YEAR 1965 *=SIMULATED +=OBSERVED

PRIMARY PARAMETERS

Period used:
31 Jul 1965 to 29 Sep 1965
(61 days)

$$K_p = (Q_p / q_p) 1/t$$

$$K_p = \left(\frac{0.041 \text{ mm}}{0.049 \text{ mm}} \right) 1/61 = 0.997$$

$$LZPK = 1 - K_p = 1 - 0.997 = 0.003$$

From an investigation of the hydrograph for 1965, it appears that the maximum primary baseflow was approximately 0.100 mm on 1 Jan 1965. Thus:

LZPK = Maximum primary Flow
LZPK = 0.100 mm = 33 mm
LZPK = 0.003 mm

SEMI-LOG MEAN DAILY FLOW PLOT(MM) SOUTH YAMHILL NR WHI WATER YEAR 1963 **=SIMULATED +=OBSERVED

UPPER ZONE TENSION WATER MAXIMUM (UZTWM)

From a review of small storms following dry periods (data listed in text of report), a value of 35 mm was selected as representing the lower limit of the maximum amount required by upper zone tension water before overflow occurs, from the upper zone.

UPPER ZONE FREE WATER DRAINAGE RATE (UZK)

Interflow for the South Yamhill appears to last about 7 days.

Using $N = 7$ in the following equation:

$$(1 - UZK)^N = 0.10$$

an approximate value of 0.3 is obtained for UZK.

UPPER ZONE FREE WATER MAXIMUM (UZFWM)

The unit hydrograph for the basin indicates a fair delay in water actually reaching the channel. Thus, a considerable portion of the water during the interflow period originally developed as direct and surface runoff. In reviewing the storm period of 22 Jan to 3 Feb 1965, the flow on 31 Jan was about 25 mm, of which about 10 mm would be baseflow and about half of the remainder delayed surface and direct runoff. (See page B-3.) With a UZK value of 0.3, we would obtain a value of about 25 mm for UZFWM $(8/0.3)$.

PERCENTAGE DIVISION OF PERCOLATION (PFREE)

Hydrographs of storms having surface runoff following long dry periods were analyzed. For these conditions, UZFW was completely filled and some water could have been available for percolation. For the South Yamhill, the baseflow after such storms appeared to be much higher than prior to the storm. Therefore, a rather large value (0.5) was assigned for PFREE as compared to the average value of 0.3.

PERCENTAGE OF BASIN COVERED BY STREAMS, ETC. (SARVA)

From maps, this was estimated to be 0.01 of the basin.

LOSS ALONG STREAM CHANNEL (SSOUT)

No evidence of loss from baseflow hydrograph. Use zero.

SIDE, ADIMP, and RSERV

Nominal starting values were used for these parameters:

$$(SIDE = 0.0; ADIMP = 0.01; \text{ and } RSERV = 0.30)$$

PERCOLATION PARAMETERS (ZPERC and REXP)

A daily maximum percolation rate curve (with upper zone storages UZTW and UZFW at maximum) was developed for the basin (fig. B-1). PBASE was computed as 9.819 mm from the equation:

$$PBASE = LZFPM * LZPK + LZFSM * LZSK$$

Calculations of parameters used in this equation were developed on pages B-2 and B-3. Based on experience with other basins, a value of approximately 90 was selected for the maximum percolation rate (for the conditions as stated).

For completely dry lower zone conditions (lower zone 100% deficient), the maximum rate is defined as:

$$\text{Maximum rate} = (1 + ZPERC) * PBASE$$

$$90 \text{ mm} = (1 + ZPERC) * 9.819$$

$$ZPERC = \frac{90 - 9.819}{9.819} = 8.17$$

A value of eight was selected for ZPERC and the nominal initial value of 1.80 was used for REXP.

DICTIONARY FOR SUBROUTINE LAND...NWS.HRL. VERSION 9/11/75

 SYMBOL ... EXPLANATION

F ... MEAN SEASONAL POT-EVAP CURVE ARRAY
 I ... INDEX
 BF ... BASE FLOW
 EP ... DAILY EVAPORATION
 E1 ... EVAP FROM UPPER ZONE TENSION WATER
 E2 ... EVAP FROM UPPER ZONE FREE WATER
 E3 ... EVAP FROM LOWER ZONE TENSION WATER
 E4 ... EVAP FROM STREAM SURFACES AND RIPARIAN VEGETATION
 E5 ... EVAP FROM ADDITIONAL IMPERVIOUS AREA
 IC ... INDEX
 PE ... POTENTIAL EVAPORATION ARRAY
 PL ... INITIAL PARAMETER VALUE ARRAY
 PX ... PRECIPITATION ARRAY
 RO ... RUNOFF ARRAY
 SL ... ARRAY CONTAINING MONTHLY TOTALS OF VARIOUS COMPONENTS
 TA ... VARIABLE IN COMMON
 VL ... ARRAY CONTAINING SOIL MOISTURE STORAGE VOLUMES
 AID ... AREA IDENTIFICATION
 BAL ... WATER BALANCE
 DEL ... INCREMENTAL VOLUME OF WATER
 DUZ ... UPPER ZONE FREE WATER DEPLETION COEFFICIENT
 EFC ... EVAP ADJUSTMENT FACTOR
 HPL ... RATIO $LZFPM / (LZFPM + LZFSM)$
 IDA ... DAY INDEX
 ID1 ... FIRST DAY
 ID2 ... LAST DAY
 IPT ... VARIABLE IN COMMON BLOCK ONLY
 IP1 ... FIRST PERIOD OF FIRST DAY
 IP2 ... LAST PERIOD OF LAST DAY
 IP6 ... SIX HOUR PERIOD INDEX
 IRG ... INDEX
 NQ6 ... VARIABLE IN COMMON BLOCK ONLY
 PAV ... MOISTURE IN EXCESS OF UZTW REQUIREMENTS
 PEG ... POTENTIAL EVAPORATION OPTION VARIABLE
 PX6 ... SIX-HOUR PRECIPITATION
 RED ... RESIDUAL EVAPORATION DEMAND
 SBF ... SUPPLEMENTAL BASE FLOW
 SIF ... INTERFLOW
 SNF ... VARIABLE IN COMMON ONLY
 SSF ... VARIABLE IN COMMON ONLY
 TBF ... TOTAL BASE FLOW
 TCI ... TOTAL CHANNEL INFLOW
 TET ... TOTAL EVAPOTRANSPIRATION
 UZK ... UPPER ZONE DRAINAGE PARAMETER
 YR1 ... FIRST YEAR
 YR2 ... LAST YEAR

AREA ... AREA NAME
 BECC ... BASE FLOW CHANNEL COMPONENT
 DEFR ... LOWER ZONE MOISTURE DEFICIENCY RATIO
 DINC ... LENGTH OF SOIL MOISTURE ACCOUNTING TIME INTERVAL IN DAYS
 DLZP ... LOWER ZONE PRIMARY STORAGE DEPLETION COEFFICIENT
 DLZS ... LOWER ZONE SUPPLEMENTAL STORAGE DEPLETION COEFFICIENT
 EFCT ... EVAPORATION ADJUSTMENT FACTOR
 FPID ... VARIABLE IN COMMON BLOCK --- FLOW POINT I.D.
 IGPE ... POTENTIAL EVAP DATA OPTION VARIABLE
 LAND ... SUBROUTINE NAME
 LAST ... VARIABLE IN COMMON BLOCK ONLY
 LZPK ... LOWER ZONE PRIMARY STORAGE DRAINAGE PARAMETER
 LZSK ... LOWER ZONE SUPPLEMENTAL STORAGE DRAINAGE PARAMETER
 MOIN ... VARIABLE IN COMMON ONLY
 MOSM ... MONTHS FOR WHICH A DETAILED SOIL MOISTURE OUTPUT IS REQUESTED
 NINC ... NUMBER OF INTERVALS IN ONE 6-HR PERIOD USED FOR SOIL MOISTURE
 ACCOUNTING
 NPTS ... VARIABLE IN COMMON ONLY
 NQ24 ... VARIABLE IN COMMON ONLY --- NUMBER OF DAILY FLOW TIME SERIES
 NTAG ... VARIABLE IN COMMON ONLY---NUMBER OF AIR TEMPERATURE TIME SERIES
 NWE6 ... VARIABLE IN COMMON ONLY ---NUMBER OF WATER EQUIV. TIME SERIES
 OFW6 ... VARIABLE IN COMMON ONLY
 PEID ... VARIABLE IN COMMON ONLY
 PERC ... PERCOLATION RATE
 PINC ... AMOUNT OF AVAILABLE MOISTURE FOR EACH INCREMENT
 PLOT ... VARIABLE IN COMMON ONLY
 PXID ... VARIABLE IN COMMON ONLY
 Q6ID ... VARIABLE IN COMMON ONLY
 REXP ... EXPONENT IN PERCOLATION EQUATION
 SDR0 ... 6-HR SUMMATION OF DIRECT RUNOFF
 SETT ... MONTHLY SUMMATION OF EVAPOTRANSPIRATION
 SFW6 ... VARIABLE IN COMMON ONLY
 SIDE ... PARAMETER SEPARATING CHANNEL AND NON-CHANNEL INFLOW
 SNOW ... SNOW OPTION VARIABLE
 SPET ... MONTHLY SUM OF POTENTIAL EVAPORATION
 SPRT ... MONTHLY SUM OF PRECIPITATION
 SROT ... MONTHLY SUM OF RUNOFF OR TOTAL CHANNEL INFLOW
 SSUR ... MONTHLY SUM OF SURFACE RUNOFF
 STAT ... VARIABLE IN COMMON ONLY
 STDA ... VARIABLE IN COMMON ONLY
 STP6 ... VARIABLE IN COMMON ONLY
 UFW6 ... VARIABLE IN COMMON ONLY
 YEAR ... CURRENT YEAR
 YRIN ... VARIABLE IN COMMON ONLY

ADDRO DIRECT RUNOFF FROM AREA ADIMP
 ADMIC ADDITIONAL IMPERVIOUS AREA STORAGE
 ADIMP ADDITIONAL IMPERVIOUS AREA
 ADSUR SURFACE RUNOFF FROM PORTION OF ADIMP NOT PRODUCING ADDRO
