

Supplement of

The AeroCom evaluation and intercomparison of organic aerosol in global models

K. Tsigaridis et al.

Correspondence to: K. Tsigaridis (kostas.tsigaridis@columbia.edu) and M. Kanakidou (mariak@chemistry.uoc.gr)

1 All measurements used in the present study are visualized in Fig. S 1, interpolated in a 5°x5° grid
2 in Fig. S 2 and the total count of data per 5°x5° grid in Fig. S 3.

3 The median, 25/75% and 9/91% of POA emissions, SOA chemical production and total OA sources
4 (POA emissions + SOA chemical production), as well as their normalized seasonal variability per
5 model, are presented in Fig. S 4. Similarly, the POA/SOA/OA load is presented in Fig. S 5, the
6 dry/wet OA deposition in Fig. S 6, the POA/SOA/OA lifetime in Fig. S 7, and the clear-sky AOD
7 at 550 nm in Fig. S 8.

8 The annual mean OA surface concentration by all models is presented in Fig. S 9, the scatterplot
9 between modeled and measured OC in Fig. S 10 and for OA in Fig. S 11.

10 The seasonal variability of OC chemical composition for the models not presented in the main
11 paper are shown in Fig. S 12 for Finokalia, Greece (remote), Fig. S 13 for Welgegung, South Africa
12 (remote), Fig. S 14 for Alaska, USA (remote), Fig. S 15 for Manaus, Brazil (remote), and Fig. S
13 16 for Amsterdam Island, Indian Ocean (marine). Also presented are the seasonal variability of the
14 OA chemical composition for the models not presented in the main paper in Fig. S 17 for Finokalia,
15 Greece (remote), Fig. S 18 for Welgegung, South Africa (remote), Fig. S 19 for Alaska, USA
16 (remote), Fig. S 20 for Manaus, Brazil (remote), and Fig. S 21 for Amsterdam Island, Indian Ocean
17 (marine).

18 In addition to the stations mentioned above, we discuss here a few additional stations. These are
19 presented in the same way as in the main paper: First their seasonal variability and the chemical
20 composition as calculated by the five models discussed in the paper, and then the calculated
21 chemical composition from the remaining ones.

22 The models are neither expected to, nor are able to capture the aerosol mass concentrations
23 measured at urban stations. They are expected, though, and are able to, perform much better at
24 remote stations, even in the vicinity of urban stations, as long as the urban plume does not
25 significantly affect the remote station measurements. The models calculate very similar aerosol
26 levels and OA chemical composition in Colorado, USA, both over an urban station (Fig. S 22) and
27 a remote one (Fig. S 23). Since the remote station is surrounded by forests, the contribution of the
28 (mostly biogenically formed) trSOC is present year-round. During summer, most models calculate
29 that trSOC dominates the total OC in that area, with contributions approaching 100% of the total

1 OC. Multiphase chemistry also contributes significant amounts of aerosols to the total OC. GISS-
2 CMU-VBS calculates that almost all POC has undergone aging, even at the urban station, probably
3 due to the very coarse model grid that does not resolve the urban core and makes the contribution
4 of the fresh urban emissions appear insignificant. CCSM4-Chem, ECHAM5-HAM2, GEOS-
5 Chem-APM and TM4-ECPL-FNP appear to calculate a higher contribution of tPOC to the total
6 OC levels; in the latter model case, this is due to the presence of primary biological particle
7 emissions. SPRINTARS, which has a very fine grid, simulates virtually all OC as trSOC at the
8 remote station, while tPOC dominates during winter at the urban station, presumably due to high
9 anthropogenic emissions that are resolved on the fine grid of that model. The same can be seen
10 with the coarser grid CCSM4-Chem model, but to a lesser extent.

11 The OA concentrations at the remote station LinAn, China (Fig. S 24), are underestimated by the
12 models. All models calculate a high contribution of tPOC to the total OC levels, a clear indication
13 of very strong regional anthropogenic pollution. Not all models agree on the trSOC contribution to
14 the total OC, with about half of the models that resolve the OC chemical composition calculating
15 a contribution that approaches 50% during summer, and the other half calculating a much smaller
16 contribution. IMPACT and IMAGES suggest that a significant amount of OC comes from
17 multiphase chemistry, while the two TM4-ECPL models do not. Recall that TM4-ECPL has a more
18 detailed aqueous chemistry scheme than the other two models, which probably explains the
19 difference in the results.

20 A region where biomass burning is also important is the Amazon basin. Alta Floresta, Brazil (Fig.
21 S 25), is a site with very long-term measurements and a clear biomass burning peak during the dry
22 season, which the models reproduce quite successfully, with the exception of GMI that peaks
23 during May. Two other models, BCC and IMPACT, do not capture the dry season peak, which
24 shows potential problems with their biomass burning emissions in the region. Care has to be taken
25 regarding the year simulated and compared with measurements. Through the years Alta Floresta
26 has experienced a significant reduction in biomass burning intensity in the region, while the data
27 shown in are the climatology of all years of measurements. During the biomass burning period,
28 GISS-CMU-VBS simulates equal amounts of fresh and aged POA, reflecting the close vicinity of
29 POA sources. Multiphase chemistry appears not to play a significant role here, in contrast with the
30 Manaus station, Brazil (Fig. 22), where IMPACT and IMAGES calculate significant amounts of

ntrSOA; the location of the inter-tropical convergence zone (ITCZ) and the potentially very different availability of cloud and aerosol water at these stations appears to be the reason behind this important difference. At the same station, many models also calculate large amounts of trSOA during the dry season.

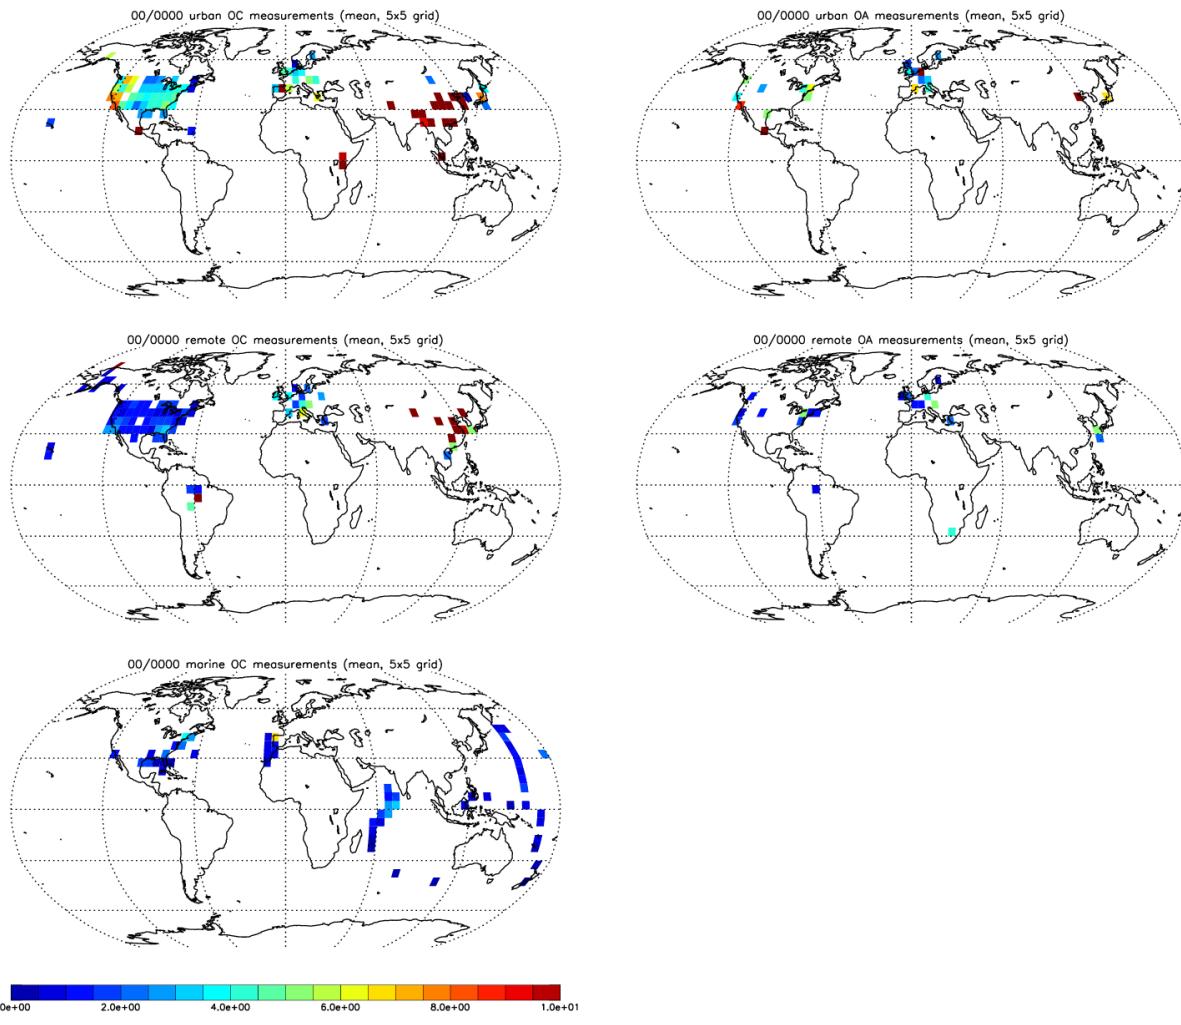

In Melpitz, Germany (Fig. S 26), most models agree that there is no clear seasonality, other than a winter and a weak summer peak. The measurements do not present a clear seasonality either, although the spread of the concentrations is larger than that calculated by most models, and there are gaps in the data that make the comparison more difficult. In any case, emissions during winter appear to be significant, although fossil fuel emissions from different models are not the same (e.g. IMPACT vs. TM4-ECPL-F, where the models calculate very similar distributions with different absolute amounts due to different emission inventories). GISS-CMU-VBS has almost no POA, either fresh or aged; the calculated OA is mostly trSOA, which is present during summer in the models. Multiphase chemistry also forms a significant fraction of the total OC. TM4-ECPL-FNP calculates a high contribution from primary biological particles, but its seasonality does not agree with that of the measurements.

The Mace Head station on the west coast of Ireland (Fig. S 27) receives mostly oceanic air masses. Among the models that include an mPOA source, GISS-modelE-G/I and IMPACT exceed the measured OA, except a high value in May, which might be either an outlier or something related to a source that the models are unable to capture. Among the other models that include mPOA, CAM4-Oslo has a mPOA source (added to tPOA) that follows the offline sea salt fluxes from AeroCom phase I (not the ones calculated online in the model) and TM4-ECPL-F/FNP have a low global flux; these models are closer to the measurements than the rest of the models that include mPOA. The models that do not include any mPOA parameterization calculate much lower OA concentrations. Products from multiphase chemistry are also present, while primary anthropogenic and biomass burning aerosols are virtually absent. Caution has to be taken because Mace Head is at the coast; many models that have their gridbox edge at 10°W use a continental box for representing Mace Head (longitude 9.9°W), which might not be representative for its predominantly marine environment.

Okinawa, Japan (Fig. S 28), is a remote marine site that is influenced by long-range transport of pollution aerosol from East Asia. AMS measurements at four different months suggest that 2-3 ug

1 m-3 are present over Okinawa, an amount that only models that include either multiphase chemistry
2 of organics, or mPOA sources, or both, can reproduce. IMAGES appears to agree best with
3 measurements, and the two TM4-ECPL models, although having both ntrSOA and mPOA, are
4 rather low. All models agree that there is a minimum in OA concentrations during summer, but
5 unfortunately no data are available to validate this trend. Small but significant OA amounts come
6 from multiphase chemistry. The models also calculate an important contribution of very aged POA.
7 The OA chemical composition from the AMS perspective for the above mentioned stations for five
8 models (as presented in the main text) is shown in Fig. S 29 for Colorado, USA (urban), Fig. S 30
9 for Colorado, USA (remote), Fig. S 31 for LinAn, China (remote), Fig. S 32 for Alta Floresta,
10 Brazil (remote), Fig. S 33 for Melpitz, Germany (remote), Fig. S 34 for Mace Head, Ireland
11 (remote), and Fig. S 35 for Okinawa, Japan (marine). In addition, the chemical composition for the
12 remaining models that have more than one organic aerosol tracer are presented for OC in Fig. S 36
13 for Colorado, USA (urban), Fig. S 37 for Colorado, USA (remote), Fig. S 38 for LinAn, China
14 (remote), Fig. S 39 for Alta Floresta, Brazil (remote), Fig. S 40 for Melpitz, Germany (remote),
15 Fig. S 41 for Mace Head, Ireland (remote), and Fig. S 42 for Okinawa, Japan (marine), and for OA
16 in Fig. S 43 for Colorado, USA (urban), Fig. S 44 for Colorado, USA (remote), Fig. S 45 for LinAn,
17 China (remote), Fig. S 46 for Alta Floresta, Brazil (remote), Fig. S 47 for Melpitz, Germany
18 (remote), Fig. S 48 for Mace Head, Ireland (remote), and Fig. S 49 for Okinawa, Japan (marine).
