Acknowledgments

The authors wish to thank Chris Chamberlin, Joint Institute for the Study of the Atmosphere and Ocean, for his help in developing the ports of Los Angeles and Long Beach numerical grids. We also thank A. E. Cannon, Technical Writer with Telcordia Technologies, Inc. and Ryan Layne Whitney, National Oceanic and Atmospheric Administrations, for providing technical assistance and for editorial review. Collaborative contributions of the National Geophysical Data Center, and the National Data Buoy Center were invaluable.

Funding for this work was provided by the Alfred E. Alquist Seismic Safety Commission under contract number 50ABNR200053. This publication was partially funded by the Joint Institute for the Study of the Atmosphere and Ocean (JISAO) under NOAA Cooperative Agreement No. NA17RJ1232, JISAO Contribution No. 1816. This is PMEL Contribution No. 3532.

Executive Summary

TSUNAMIS HAVE BEEN RECOGNIZED as a potential hazard to United States coastal communities, harbors, and ports, including those in the State of California, since multiple destructive events impacted California's coast in the mid-twentieth century. In response, the United States National Oceanic and Atmospheric Administration began a tsunami research program at the Pacific Marine Environmental Laboratory to develop tools for measuring, modeling, and assessing the hazard posed by tsunamis. The destruction and unprecedented loss of life following the December 2004 Sumatra tsunami served as the catalyst to refocus these activities, and on 20 December 2006, the United States Congress passed the "Tsunami Warning and Education Act." The act mandated specific education and warning activities and dedicated resources to accelerate the pace of tsunami product development, including those applicable to comprehensive hazard assessment of coastal communities.

The State of California shares longer than 1,300 km of coastline with the tectonically active Pacific Ocean. Along the southern portion of this coastline, in Los Angeles County, reside two of the busiest container ports in the United States: the Port of Los Angeles and the Port of Long Beach. Adjacent to one another, the ports combine to be the fifth busiest in the world, handling more than 10 million containers annually and providing 30,000 jobs which, in turn, support the local economy. Greater than 300,000 jobs in a five-county area in Southern California are tied to the ports, as are an estimated 1.1 million jobs throughout the state. In addition, the contribution of the ports to the economy of California and to the United States as a whole is significant. Annual state and local tax revenue exceeds \$5 billion (Port of Los Angeles, 2009; Port of Long Beach, 2009; Coastal Conservancy, 2009).

A tsunami impact to the ports of Los Angeles and Long Beach would potentially cause significant damage and disrupt port operations for an extended period of time. The tsunami generated by the 1964 Great Alaska Earthquake caused strong surges that tore 75 small vessels from their moorings and sank three boats in the ports of Los Angeles and Long Beach. Potential damage to the ports, and the disruption that would likely occur today, would have severe repercussions for the economy of the State of California, which relies heavily on port activities for revenue, trade, and employment. Past events and comprehensive studies of the region have documented the seismic history of the Southern California coastal region and point to the potential hazard from tsunamis. A detailed sensitivity study has been performed with synthetic tsunamis generated by Mw 9.3 earthquakes along Pacific Ocean subduction zones to identify probable maximum tsunamis. A total of 56 scenarios generated from sources along the Alaska-Aleutian subduction zone, 106 from Central and South America, 13 from the Nankai Trough and Ryuku, 28 from the Solomons and Vanuatu, 30 from New Zealand, 6 from New Guinea, 8 from Manus, 66 from the Kurils and Mariana, and 9 from the Eastern Philippines, for a total of 322 synthetic scenarios, were investigated. Of these 322 scenarios, tsunamis from 11 source regions in Alaska, Chile, Philippines, Manus, New Zealand, and Vanuatu are identified as having the potential to generate a tsunami

significant to the ports of Los Angeles and Long Beach, so these are investigated in detail. Study results suggest that Mw 9.3 earthquakes can trigger a tsunami with wave amplitude reaching up to 2 m (≈ 6.5 ft) and currents exceeding 8 knots (≈ 4 m/s) in the ports of Los Angeles and Long Beach. Currents are particularly noteworthy since those exceeding 8 knots (≈ 4 m/s) are known to break mooring lines and damage harbor piers and other structures.

Tsunami Hazard Assessment Special Series: Vol. 2

Distant tsunami threats to the ports of Los Angeles and Long Beach, California

B. Uslu^{1,2}, M. Eble², V.V. Titov², and E.N. Bernard²

1. Introduction

Los Angeles County hosts two container ports adjacent to one another in San Pedro Bay that are operated separately by the cities of Los Angeles and Long Beach. The satellite image shown in **Figure 1.1** provides a view of San Pedro Bay in which each port and harbor system is distinguished from the other. Although the ports compete for business, they are the two busiest container ports in the United States and together combine as the world's fifth busiest (15.7 million total TEU [Twenty-Foot Equivalent Unit]), following the ports of Singapore (27.9 million TEU), Shanghai (26.2 million TEU), Hong Kong (23.9 million TEU), and Shenzhen, China (21.1 million TEU). The ports contribute significantly to the economy of California and to the United States as a whole. Annual state and local tax revenue exceeds \$5 billion. The contribution of trade to the economy of California is approximately \$58 billion and approximately \$20 billion throughout the entire United States (Port of Los Angeles, 2009; Port of Long Beach, 2009; Coastal Conservancy, 2009).

A deterministic tsunami hazard assessment is provided for the ports of Los Angeles and Long Beach. The goal of this assessment study is to identify probable maximum tsunamis (tsunamis with potential high impact) by investigating many possible source scenarios under which a magnitude Mw 9.3 earthquake would generate a tsunami with impact on the ports. This work leverages previous investigations (Borrero *et al.*, 2004; Borrero, 2002; Borrero *et al.*, 2001) of the near-field fault line sources of Santa Catalina Island, Santa Monica, Newport-Inglewood, and San Mateo, as well as landslide sources from the Channel Islands and off of Palos Verdes (**Figure 1.2**). Later investigations conducted by Moffatt and Nichol expanded these studies to include Cascadia sources. Prior to the November 2006 Kuril Island event, most studies focused on wave heights as the dominant measure of hazard. However, the impact of the Kuril Island tsunami on Crescent City demonstrated that distant sources have the potential of inducing strong currents with small amplitude waves in harbors that can cause substantial damage. The Tsunami Forecast Database of tsunami source functions was used in the study to develop all tsunami propagation scenarios. Tsunami Source Functions are a collection of tsunami propagation model runs that have been pre-computed for selected locations along known and potential earthquake zones. The forecast database for the Pacific consists of over 850

Figure 1.1: Satellite image of the ports of Los Angeles and Long Beach (TerraServer-USA and USGS). The red dotted line demarks the border that separates the two ports. Model validation is based on the Los Angeles tide gauge located at Berth 60, as shown and marked in blue. The low elevations surrounding the ports of Los Angeles and Long Beach make the region vulnerable during a tsunami event. Residents of the densely populated cities of San Pedro, Harbor City, Long Beach, and Rancho Palos Verdes, along with the many tourists that visit attractions, including Cabrillo Beach Park, the Queen Mary, and the Aquarium of the Pacific, are at risk from tsunami impact.

Figure 1.2: Regional setting showing geographic features of Southern California and surrounding major offshore fault lines with respect to the ports of Los Angeles and Long Beach.

source functions, equivalent to a tsunami generated by a Mw 7.5 earthquake. These were used to develop combination sources for larger events of this study. Only the sources that can potentially produce significant impact at the studied location have been used in the high-resolution computations.

To investigate the hazard posed by currents, a sensitivity study was performed for 322 synthetic tsunami sources for Mw 9.3 earthquakes along Pacific Rim subduction zones using the Method of Splitting Tsunamis model (Titov and Synolakis, 1998). Of the scenarios investigated, 11 sources in Alaska, Chile, Philippines, Manus, New Zealand, and Vanuatu have been identified as posing the greatest risk to the ports of Los Angeles and Long Beach. There are no potential Hawaiian tsunami sources, with the exception of a catastrophic yet improbable slope failure. Consideration of such an event is not addressed as part of this study. Tsunami amplitudes are computed at the Los Angeles tide gauge for each synthetic Mw 9.3 earthquake generated as a result of a 30-m rupture on a 1000-km \times 100-km area along each subduction zone. In total, 322 scenarios are considered: 56 from Alaska/Aleutians, 106 from Central and South America, 13 from Nankai Trough and Ryuku, 28 from Solomons and Vanuatu, 30 from New Zealand, 6 from New Guinea, 8 from Manus, 66 from Kurils and Mariana, and 9 from the Eastern Philippines. Results of this study suggest that a great Mw 9.3 earthquake could potentially trigger a tsunami with wave amplitudes reaching up to 2 m (\approx 6.5 ft) and current velocities exceeding 4 m/s (\approx 8 knots) inside the harbors in which the ports of Los Angeles and Long Beach are located. Study results also suggest that Pacific Basin subduction zones in addition to those in Alaska and along the Aleutians and Cascadia are capable of generating tsunamis that pose a threat to the ports of Los Angeles and Long Beach.

1.1 Review of earlier work

The first detailed study of the hazard posed to California by tsunamis generated in the far field was conducted by Houston and Garcia (1974). In this study, the 100-yr and 500-yr tsunami runup heights for selected locations along the California coastline were computed using a combination of numerical and analytical methods. Tsunamis generated in both the Alaska-Aleutians subduction zones and the South America Subduction Zones, based on the 1964 Great Alaska and 1960 Chilean earthquakes, were considered in the study. Houston and Garcia's approach involved breaking up the Alaska-Aleutian subduction zone into 12 discrete segments to identify "worst-case scenarios." A maximum vertical uplift of 8–10 m was assumed based on initial ground deformations due to the hypothetical uplifting of an ellipsoidal mass approximately 1000-km long having an aspect ratio of 1:5. Using a one-dimensional linear shallow-water equation in spherical coordinates, Houston and Garcia propagated their initial waves from the Alaskan and Chilean sources to California. At the continental shelf, an analytical expression was derived to match the inner- and outer-harbor wave amplitudes and obtain a simple amplification factor to produce wave amplitudes at offshore locations. Three limitations to their solution were noted. First, a one-dimensional model was applied for the solution of near-

field events. This solution, however, is not a priori appropriate for complex nearshore bathymetry, such as in narrow bays. Second, they used a sinusoidal wave in the analytical solution close to shore, but this can lead to substantial errors in the solutions of the runup. Third, small-scale nearshore features affect local inundation and runup to first order, but were neglected in the coarse gridded computation of Houston and Garcia (1974).

McCulloch (1985) built on the results of Houston and Garcia (1974) and Houston (1980) from far-field tsunamis. McCulloch assessed the tsunami threat using an empirical formulation that related earthquake magnitude to tsunami wave height without the use of a hydrodynamic model. Synolakis *et al.* (1997) explained that such empirical formulas were developed for use in specific locales within Japan, and, as a result, generally under-predicted the runup in other earthquake regions.

Following the 1992 Cape Mendocino earthquake and tsunami that struck the coastline within minutes of the earthquake, McCarthy *et al.* (1993) performed a systematic analysis of all available historical records to assess future tsunami hazards to California. Investigators divided California into four coastal sections and qualitatively evaluated each section according to tsunami risk. They determined the risk of tsunami as *high* along the coastline from Crescent City to Cape Mendocino, *moderate* from south of Cape Mendocino to north of Monterey, *high* from Monterey to Palos Verdes, and then *moderate* from south of Palos Verdes to San Diego. These results provided the baseline for future investigations such as that of Borrero (2002), who applied developments in numerical modeling to show the limitations of McCarthy *et al.*'s (1993) results. Synolakis *et al.* (2002) used the 1998 Mw 7.0 Papua New Guinea event, in which greater than 1000 people lost their lives, to prove that even a moderate earthquake could have a highly localized catastrophic impact as the result of a submarine landslide. This finding had been controversial for many years (Geist, 2000; 2001; Okal and Synolakis, 2001) and remained so until Borrero (2002) investigated and documented historical submarine landslides in conjunction with an inundation mapping study underway for the California Office of Emergency Services. He introduced an innovative analysis of tsunami waves from landslide sources by use of a hydrodynamic model to assign initial landslide conditions. Borrero found that the waves generated by catastrophic failures during historical events in the Santa Barbara Channel, Santa Monica and Redondo Canyons, and off the Palos Verdes Peninsula caused high but localized inundation and runup. The approach, while empirical, was gaining acceptance through preliminary validation; see Synolakis (2003).

Dykstra and Jin (2006) and Moffatt and Nichol (2007) reinvestigated the work of Borrero (2002) and computed tsunamis in the ports of Los Angeles and Long Beach. They looked at tsunamis generated in the near field coupled with two Palos Verdes landslides and three tsunamis generated along the Cascadia subduction zone. The Moffatt and Nichol report considered the Cascadia Subduction Zone as the only far-field tsunami source. Uslu (2008) looked at Pacific-wide tsunami scenarios, including those impacting Central and Northern California, to assess a probabilistic return rate of the hazard. His work was complementary to the near-field inundation mapping work of Borrero (2002) in that far-field tsunami sources were investigated.

Prior to the Kuril 2006 earthquake and tsunami, current velocity measurements were not routinely taken inside California harbors. The only data available during and following an event were heights recorded at tide gauge stations. As a result, most studies focused on wave heights as the measure of hazard. Following the 2006 Kuril Islands tsunami, eye witness accounts in Crescent City put the currents in the approximate range of 10 knots inside the protected harbor. This Kuril 2006 tsunami caused greater than \$10 million damage to Crescent City (Dengler *et al.*, 2008; Kelley *et al.*, 2006; Uslu, 2008). Observed currents in Crescent City Harbor following this 2006 event showed, contrary to previous studies, that a tsunami generated in the far field has the potential to induce small amplitude waves with large and, consequently, destructive currents in harbors. With this in mind, the goal of this study is to provide a tsunami hazard assessment for the California ports of Los Angeles and Long Beach that includes both maximum amplitudes and current velocities. Earthquake sources in the far field from which tsunamis are generated and expected to have the greatest impact on the activities and economy of the ports are identified.

2. Background

2.1 The tsunami history of California

Studies have shown that tsunamis triggered by similar magnitude earthquakes along dissimilar subduction zones may result in substantially different impact at the same harbor (Dengler *et al.*, 2008; Kelley *et al.*, 2006; Uslu, 2008). The Kuril Islands earthquakes of 1933, 1994, 2006, and 2007 were of similar magnitudes and similar source locations, but produced different far-field impact due to fault orientation differences. The events of 1933 and 2006 were thrust fault earthquakes, and the 2007 earthquake had a normal fault mechanism. The 1994 earthquake was described as a vertical tear in the slab near the Hokkaido corner by Tanioka *et al.* (1995), but has been successfully modeled as a thrust fault in Uslu (2008) and Dengler *et al.* (2008).

Table 2.1 provides a list of historical earthquakes that generated damaging Pacific-wide tsunamis and had a significant impact on the California coastline since 1868. No data are available during most of these events, but observations recorded at the time of the 1952 Kamchatka, 1960 Chile, 1964 Great Alaska, and 2006 Kuril Islands events are used in the hazard assessment of the ports of Los Angeles and Long Beach. Two of these events, the 1960 Chile and the 1964 Great Alaska, are particularly noteworthy. In 1960, a large Mw 9.5 earthquake in Chile generated a tsunami that propagated northward and caused greater than \$1 million in damage to the Port of Los Angeles. The tsunami also struck Santa Barbara and broke the mooring lines of a dozen vessels and destroyed a 50-m dock in San Diego (Lander *et al.*, 1993).

Table 2.1: List of significant far-field generated tsunamis that have affected California (Lander *et al.*, 1993). Seismic moments updated (Okal, 1992, personal communication, 2007).

Date	Source	Mw	Damage/Effect
1868	Peru	9.3	Minor flooding in San Pedro and Wilmington
1896	Japan	8.0–8.6	Damage in Santa Cruz
1906	Ecuador	8.3	Ships caught in eddies in San Francisco
1922	Chile	8.3	Strong currents
1923	Kamchatka	8.4	Shipping affected in Los Angeles
1946	Aleutian Islands	8.6	90-cm tsunami in Crescent City, broken moorings in northern California and one fatality.
1952	Kamchatka	9.0	4 boats sunk in Crescent City
1957	Aleutian Islands	8.3–8.6	Damage to ships and docks in San Diego
1960	Chile	9.5	\$1 million damage in LA Harbor
1964	Alaska	9.2	\$17 million damage +12 fatalities
1965	Aleutian Islands	8.7	60-cm sea level rise in Santa Cruz
1975	Hawaii	7.2	Minor damage to a dock on Catalina Island.
2006	Kuril Islands	8.3	\$9.7 million in damage in Crescent City

The Mw 9.3 1964 Great Alaska Earthquake and tsunami caused eleven fatalities, ten of which were drowning deaths in the Northern California community of Crescent City. Damage from this tsunami was estimated at greater than \$17 million in California (Lander *et al.*, 1993). The waterfront and 29 city blocks of Crescent City were damaged or destroyed, with total damage estimated at \$15 million. The tsunami was recorded on tidal gauges statewide and caused approximately \$1 million damage at various marinas inside San Francisco Bay, including Sausalito, San Rafael, and Berkeley. The tsunami also caused strong surges that tore 75 small vessels from their moorings and sank 3 boats in the ports of Los Angeles and Long Beach even without high waves. Unconfirmed reports from Ventura Harbor suggest that the tsunami damaged several vessels (C.E. Synolakis, personal communication, 2007). There were also reports of strong surges and a water level rise of 2 m in San Diego (Lander *et al.*, 1993).

Other notable events impacting Southern California include the Mw 8.6 1946 Aleutian Islands earthquake. The tsunami carried boats one quarter mile inland in Half Moon Bay, washed away a pier on Catalina Island, broke ship moorings in Los Angeles, and caused minor damage in Santa Cruz. The Mw 9.0 1952 Kamchatka tsunami capsized five small boats and moved a 60-ton mooring buoy in Crescent City. This tsunami also caused damage in Santa Cruz. The Mw 8–8.6 1896 Sanriku earthquake in Japan generated a tsunami that propagated across the Pacific. It destroyed a dike and caused damage to a ship anchored in Santa Cruz (Lander *et al.*, 1993).

The 2006 Kuril Islands tsunami clearly impacted the California coastline with the set-up of currents that damaged Docks E, G, and H in the small boat basin within Crescent City harbor, shown in **Figure 2.1** (Dengler *et al.*, 2009). In addition, other earthquakes generated tsunamis that caused strong currents. The 1960 Ecuador tsunami was observed with strong currents in San Diego and San Francisco (Soloviev and Go, 1974), and the 1923 Kamchatka tsunami was recorded with 105 cm wave height at the San Diego tide gauge and 20 cm wave height at the San Francisco tide gauge, and the shipping was greatly affected in Los Angeles because of strong currents (Lander *et al.*, 1993).

On 29 September 2009, a Mw 8.0 earthquake occurred 195 km (125 miles) south of Apia, Samoa, at 17:48 UTC (USGS, 2009). The tsunami was recorded at the Los Angeles tide gauge approximately 11 hr later with a height of approximately 25 cm (≈ 10 in), but did not cause any significant damage to the ports of Los Angeles and Long Beach. **Figure 2.2**, provided by WCATWC (2009), shows the observed tsunami signal following the 2009 Samoa tsunami as recorded at the Los Angeles tide station. The red line is the signal as observed, the blue line shows the predicted tide, and the green line is the de-tided record showing the isolated tsunami signal.

On 15 November 2006, a tsunami generated by a Mw 8.3 earthquake occurring along the Kuril Islands subduction zone caused significant damage to Crescent City. This event was followed closely in time by a Mw 8.1 earthquake and tsunami on 13 January 2007. One decade prior to these events, a tsunami was generated by a Mw 8.3 earthquake that occurred 4 October 1994. Significantly, these earthquakes all had different fault mechanisms even though they occurred adjacent to one another along the Kuril Islands subduction zone. The 2006 event was a classic inter-plate thrust mechanism. The 2007 earthquake

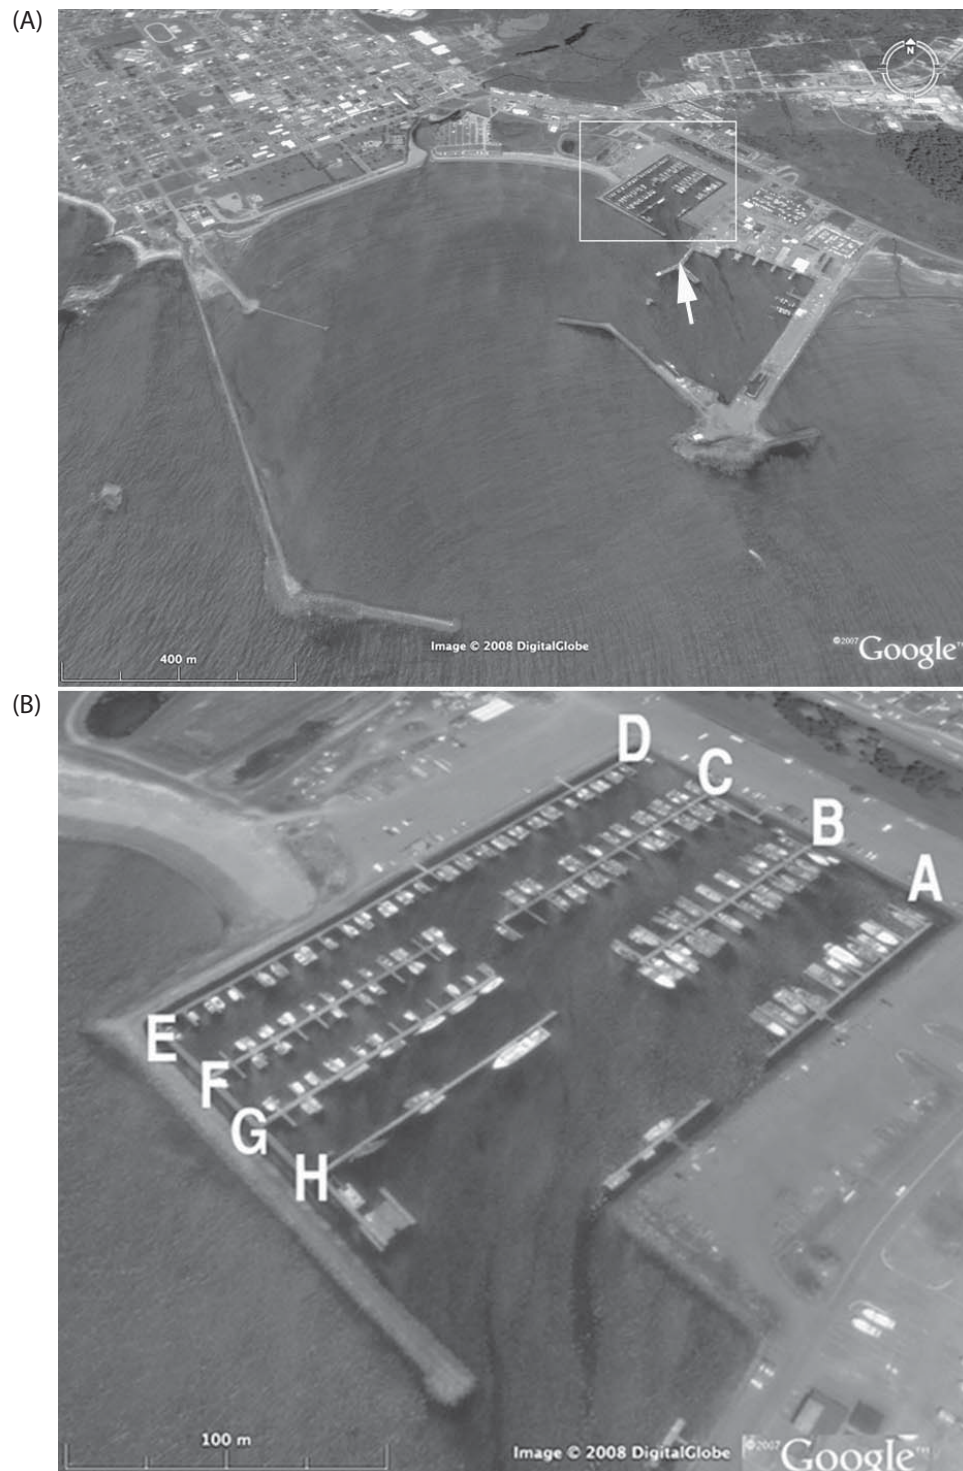

Figure 2.1: A Google Earth view of Crescent City and Crescent City Harbor. The upper figure shows Crescent City with the white box marking the small-boat basin, and the lower figure shows the small boat basin, where the Docks F, G, and H were damaged during the 2006 Kuril Islands Tsunami (Dengler *et al.*, 2009).

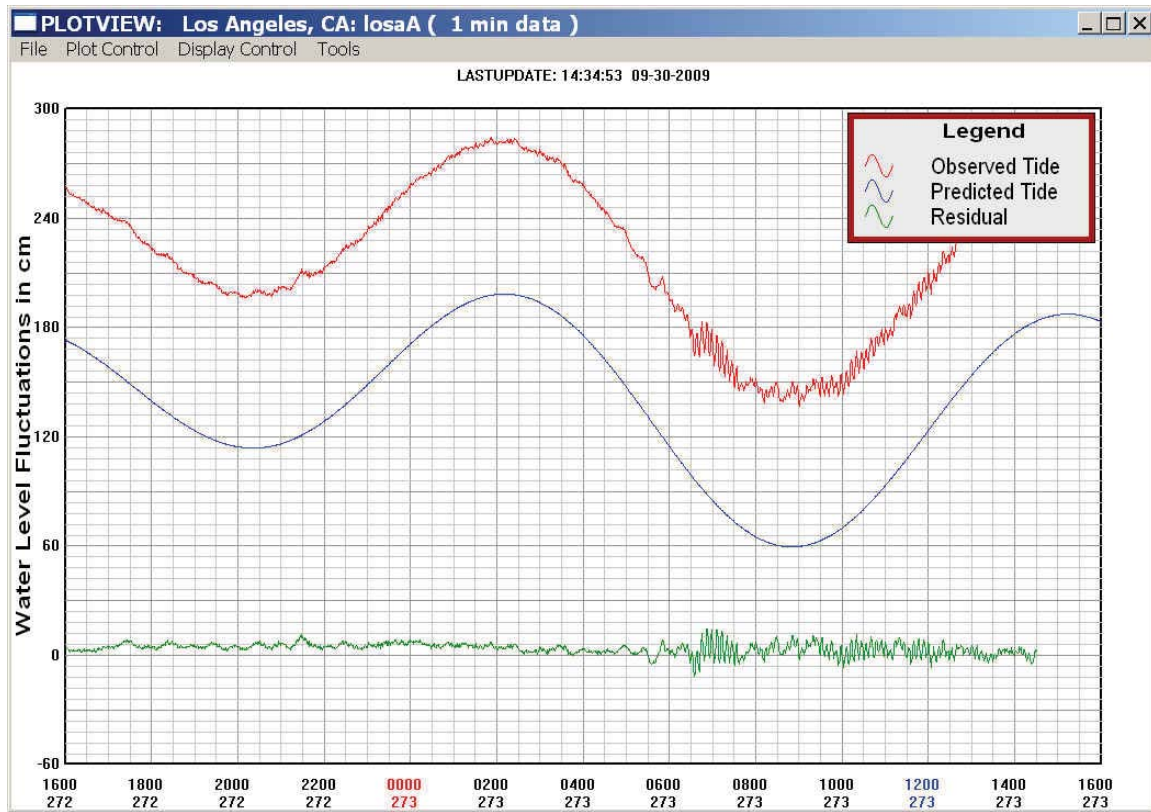

Figure 2.2: 2009 Samoa tsunami recorded at the Los Angeles tide gauge, provided by WCATWC (2009).

involved normal faulting in the outer rise, probably triggered by stress transfer from the 2006 earthquake. The 1994 earthquake resulted from a slip on a relatively deep (68 km) vertical tear in the slab near Hokkaido, Japan (Tanioka *et al.*, 1995). The difference in earthquake mechanism is particularly significant since all three events generated tsunamis with diverse characteristics. The 1994 Shikotan tsunami ran up locally 5 to 9 m (16–30 ft) and inflicted significant damage to the coast of the southern Kuril Islands (Yeh *et al.*, 1995). A tsunami of amplitude 30 cm (1 ft) was recorded at the Crescent City, California, tide gauge following the 1994 event. The 2007 tsunami amplitude was recorded as 25 cm at the Crescent City tide gauge.

The Mw 8.3 15 November 2006 earthquake occurred at approximately 11:14 (UTC) offshore of the central Kuril Islands of Simushir, Rasshua, and Matua, which are uninhabited and inaccessible during the winter months. Therefore, the local tsunami impact on these islands remained unknown until 2007 field work conducted during the summer season revealed runup of up to 21 m (69 ft) on Matua (MacInnes *et al.*, 2009; Levin *et al.*, 2008). On Hokkaido Japan, the November 2006 tsunami reached Hanasaki in 64 min and was measured at Japanese tide gauges as 0.5 m (≈ 1.5 ft). As a result, a large tsunami was not anticipated in Alaska nor along the U.S. Pacific coast, yet, on the afternoon of 15 November 2006, Crescent City was hit by a series of strong waves, extensively damaging three of the eight docks in the harbor.

Figure 2.3: Map of the Cascadia Subduction Zone, the Juan de Fuca, Gorda, and Pacific Plates (modified from Satake *et al.*, 2003). Cascadia extends northward from Northern California to just north of Vancouver Island in British Columbia, Canada.

The impact on Northern California of tsunamis generated along the Cascadia Subduction Zone has been discussed by Uslu *et al.* (2007). The Cascadia Subduction Zone extends from Cape Mendocino, California, in the south and beyond Vancouver Island in the north, for a total length of 1000 km, as shown in **Figure 2.3**. The Cascadia Subduction Zone is marked by a variable subduction rate, approaching 4 cm/yr where the Juan de Fuca plate dives beneath the North American plate in the vicinity of Washington State (Satake *et al.*, 2003). A slower rate of subduction, 3 cm/yr, is noted at the northern end of the Gorda plate offshore of northern Oregon (Wang *et al.*, 2001). Near the Mendocino triple junction in Northern California where the Gorda Plate terminates, the rate of subduction approaches zero (Clarke and Carver, 1992). A rupture along the Gorda Plate offshore of Southern California poses a great risk to Northern California, but a comparably smaller threat to the coastlines of Central and Southern California.

Satake *et al.* (1996; 2003) identified a historically reported tsunami in Honshu, Japan, in the year 1700. They used coastal subsidence data coupled with numerical simulations to infer that the tsunami was generated at approximately 05:00 (UTC) on 27 January 1700 by a Mw 9.0 Cascadia Subduction Zone earthquake (Uslu *et al.*, 2008). Since there are no direct seismic or geodetic observations to identify the physical behavior of the rupture zone, Wang *et al.* (2003) combined information about the 1700 A.D. earthquake with relevant data from other subduction zones and calculated windows for the potential extent of rupture, strains, rupture velocities, and uplift rates. Their approach assumed a co-seismic rupture over the entire subduction zone with an average recurrence of 500 years, which is a scenario believed to be conservative.

3. Tsunami Modeling of California Ports and Harbors

The high-resolution tsunami forecast model used for this study was previously developed for the city of Los Angeles by the NOAA Center for Tsunami Research as part of a tsunami forecasting system under development for use by NOAA's two Tsunami Warning Centers. The high-resolution models capable of simulating wave inundation on land are called inundation models. The ability of the model to reproduce moving boundary conditions (water moving on dry land) is critical to assess the impact of large tsunamis. Therefore, only inundation models should be used for the impact studies, especially if current velocities are to be reproduced, since the inundation dynamics can change the flow velocity substantially. A particular scenario may or may not produce inundation (water actually penetrating onto dry land), but the use of an inundation model is critical, since we cannot predict if this is going to happen or not. Also, the water withdrawal can be tracked only with inundation models. An optimized version of the model is developed to run efficiently in an operational environment without degradation of results. For this hazard assessment study, the high-resolution reference model was applied to the tsunami forecast model and was benchmarked using both available historical data and synthetic scenarios. The study applies the Los Angeles tsunami model to a hazard assessment of the vulnerability of the southern California ports of Los Angeles and Long Beach. Tsunami-induced currents and maximum wave amplitudes are computed following tsunami generation in the far field based on synthetic scenarios selected to quantify the expected worst case.

3.1 Methodology

Tsunamis are triggered by deformation of the seafloor or by impacts sufficient to displace large volumes of water. Underwater earthquakes are the primary generation mechanism of tsunamis, but other less common events such as volcanic eruptions, landslides, or meteor impacts can also cause tsunami waves. Once generated, a tsunami propagates away from its source throughout the ocean and then inundates vulnerable coastlines. Regardless of the mechanism, once generated, the potential impact of a tsunami to a coastal community, such as that of the southern California coast along which reside the ports of Los Angeles and Long Beach, can be modeled to provide expected wave arrival time and estimates of maximum amplitude, current velocities, and inundation.

A high-resolution inundation model was developed for Los Angeles and used as the basis for development of a complementary optimized tsunami forecast model to provide an estimate of wave arrival time, wave amplitudes, current velocities, and inundation immediately following tsunami generation. Both high-resolution and optimized tsunami forecast models are based on the

Method of Splitting Tsunami (MOST) model, which is a suite of numerical simulation codes capable of simulating three processes of tsunami evolution: earthquake, trans-oceanic propagation, and inundation of dry land. Both models were developed previously by the NOAA Center for Tsunami Research and both are used in this study.

The MOST model was validated through a series of laboratory experiments and benchmarked with numerous field surveys (Titov and Synolakis, 1997; 1998). The codes conform to the standards and procedures outlined by Synolakis *et al.* (2008) and have been used extensively for simulations of historical events prior to this study. Initial water surface elevation, evolution of wave propagation, tsunami inundation, and current velocities are computed by solving the governing non-linear shallow water equations with a finite difference algorithm (Titov and Synolakis, 1997; 1998). The initial displacement of the water surface is of profound significance in calculating the evolution of the resulting waves. It is assumed that displacement is instantaneous so the net seafloor displacement can be considered as an initial condition for the free surface. In this study, an inundation model is necessary for accurate computation of velocities due to overland flow at the coastline. Wave amplitudes and depth-averaged current velocities are computed at each grid point for every modeled time step. Runup onto the shoreline is computed by introducing moving grids to simulate the evolution on initially dry land. To arrive at the governing shallow water equations, total depth is defined as $h = \eta(x, y, t) + d(x, y, t)$, where $\eta(x, y, t)$ is the wave amplitude at the surface, and $d(x, y, t)$ is the undisturbed water depth; $u(x, y, t)$ and $v(x, y, t)$ as the depth-averaged current velocities in the onshore x and long-shore y directions, respectively; and g as the acceleration of gravity, the shallow water equations, then, are:

$$h_t + (uh)_x + (vh)_y = 0, \quad (1)$$

$$u_t + uu_x + vv_y + gh_x = gd_x, \quad (2)$$

and

$$v_t + uv_x + vv_y + gh_y = gd_y. \quad (3)$$

3.2 Propagation database

A pre-computed propagation database consisting of water level and flow velocities over all basin grid points and based on potential seismic unit sources has been developed for the world ocean basins by the NOAA Center for Tsunami Research (Gica *et al.*, 2008). Subduction zones have been broken up into fault segments, or unit sources, each measuring 100 km long by 50 km wide. The propagation database is created from each of these discrete earthquake rupture segments by computing wave propagation throughout the entire Pacific Basin. There are 403 unit sources from earthquakes of 100 km \times 100 km and 1-m rupture. **Figure 3.1** shows forecast propagation database locations with respect to the Los Angeles tide gauge. Heights and currents are computed at the Los Angeles tide station, identified in red in **Figure 3.1**. The largest earthquake since the turn of the 20th century was recorded in the Southern Chile region shown in **Figure 3.1**. Several large earthquakes occurred along the Alaska/Aleutians

Figure 3.1: Pacific Basin subduction zone propagation database unit sources shown relative to the Los Angeles tide gauge.

subduction zone in the mid-20th century, the largest of which was the 1964 Great Alaska earthquake in Prince William Sound. All earthquakes modeled for this study are assumed as occurring from a thrust fault mechanism, with the exception of the 2007 Kuril Islands event. This earthquake was due to a normal fault mechanism, yet was successfully modeled with a negative slip applied to the propagation database. Larger events are modeled by combining unit sources. A Mw 9.3 event can be modeled as a 1000-km \times 100-km rupture with a 30-m slip, which is effectively a combination of 10 Mw 7.6 events scaled up 30 times. Detailed source information for each specific subduction zone used for this study appears in Appendix C.

3.3 Numerical grids

Modeling of the ports of Los Angeles and Long Beach is accomplished by utilizing a previously developed set of three nested grids, referred to as A-, B-, and C-grids, that telescope down from a large spatial extent to a grid that finely defines the two ports in detail. Each of the three grids becomes successively finer in resolution as they telescope from offshore into the port center. The offshore

Figure 3.2: Merged nested bathymetry/topography grid locations for Southern California. Magenta boxes demarcate the forecast model grids and the grey boxes show the high-resolution reference model grids. The grids are nested; the outer grids are low resolution, and the inner grids are high resolution.

area is covered by the largest and lowest resolution C-grid, while the near-shore details are resolved within the finest scale A-grid to the point that tide gauge observations recorded during historical tsunamis are resolved. The basis for these grids is a high-resolution digital elevation model constructed by the National Geophysical Data Center using best available bathymetric, topographic, and coastal shoreline data. Data were compiled from a variety of sources to produce a digital elevation model referenced to Mean High Water in the vertical and to the World Geodetic System 1984 in the horizontal (<http://ngdc.noaa.gov/mgg/inundation/tsunami/inundation.html>). From these digital elevation models, the set of three high-resolution, nested “reference” models was constructed. A detailed discussion of grid preparation is provided by Tang *et al.* (2008a;b).

Table 3.1: Historic Tsunami Sources recorded at Los Angeles tide station (Uslu, 2008; Borrero *et al.*, 2006; 2007; Tang *et al.*, 2008b;a).

Date	Event	Time (UTC)	Mw	Lat. (°)	Lon. (°)	Source
2006-05-03	Tonga	15:26:39	8.1	20.13N	174.164W	6.6 × b29 NTSZ
1964-03-28	Alaska	03:36:14	9.2	61.04N	147.73W	10 × (400 m × 290 km)+ 10 × (400 km × 175 km)
1960-05-22	Chile	19:11:14	9.5	45.88S	76.29W	20.0 × (a88 – 97 + b88 – 97) CSSZ
1952-11-04	Kamchatka	16:58:26	9.0	52.75N	159.5E	7.0 × (a1 – 7 + b1 – 7) KISZ

The grid setup for the ports of Los Angeles and Long Beach study is shown in **Figure 3.2**. Tsunami waves pass through each of the two outermost nested grids, arriving at the innermost nested grid that contains the two ports. The resolution of each grid increases from the outer, offshore grid to the inner, harbor grid gradually. The outermost or A-grid includes the Southern California continental shelf. Two sets of model grids are used for this study: one for the high-resolution model and another for the optimized forecast model. The high-resolution model has an outer 30-arc-sec grid, middle 6-arc-sec grid, and an inner 1-arc-sec grid. The resolution of these model grids supports a detailed study of harbor resonance and inundation. The lower resolution forecast model is constructed to provide efficient computational run time, but has been benchmarked against the high-resolution model and compared with available tide gauge records. For the forecast model, the outer grid resolution is 120 arc sec, the middle grid is 12 arc sec, and the inner grid is 3 arc sec. High-resolution model grids (magenta boxes) are distinguished from forecast model grids (gray boxes) in **Figure 3.2**.

3.4 Using MOST to simulate historical events

The complexity of Southern California’s offshore regional bathymetry of the Channel Island, Santa Catalina Island, and the harbor in which reside the ports of Los Angeles and Long Beach pose challenges to the modeling of tsunamis. Numerical modeling of this region, and the investigation of historical events from the most active subduction zones in Alaska/Aleutians and Kurils to the North-Northwest of Southern California and South American subduction zones to the south, has shown that California’s offshore geology helps to dissipate tsunami energy.

Four historical tsunamis recorded by the Los Angeles tide gauge, listed in **Table 3.1**, provided case studies for use as a benchmark for this work. Historical records of wave amplitudes at the tide gauge from these four events, 1952 Kamchatka, 1960 Chile, 1964 Alaska, and 2006 Tonga, are compared to the modeled results of both the high-resolution and forecast model as shown in **Figure 3.3**. The recent Mw 8.8 Chile earthquake and tsunami provided the opportunity for additional model validation. A comparison between observation at the tide gauge and the model results for the 2010 Chile tsunami is provided in **Figure 3.4**. Computed forecast model and high-resolution model results confirm the accuracy of the forecast model. The maximum wave during the 1952 tsunami is observed as the sixth wave in the series that struck the Los Angeles tide

Figure 3.3: Time series of the 1952 Kamchatka, 1960 Chile, 1964 Alaska, and 2006 Tonga tsunamis computed at the Los Angeles tide gauge. The black line shows the time series at the tide gauge while computed time series from the high-resolution reference model and the optimized forecast model are shown in red and green, respectively.

Figure 3.4: Comparison between observations at Los Angeles tide gauge and modeled results during the recent 2010 Mw 8.8 Chile tsunami.

gauge, while the maximum tsunami wave is computed by the model to be the ninth.

4. Results

The results of a deterministic tsunami hazard assessment for the ports of Los Angeles and Long Beach are presented and discussed. The assessment utilized the validated tsunami forecast model developed for Los Angeles as specified in Chapter 3. This assessment of tsunami hazard at the two ports identifies possible worst-case scenarios from 11 far-field source regions selected as subsets of 322 synthetic case scenarios that were investigated.

4.1 Sensitivity of tsunami amplitudes at ports

Maximum computed wave amplitudes at the Los Angeles tide gauge for a total of 322 synthetically generated tsunami source scenarios around the Pacific Basin for a Mw 9.3 earthquake are shown in **Figure 4.1**. Large waves, in excess of 1.5 m (≈ 5 ft), are computed at the Los Angeles tide gauge for sources in

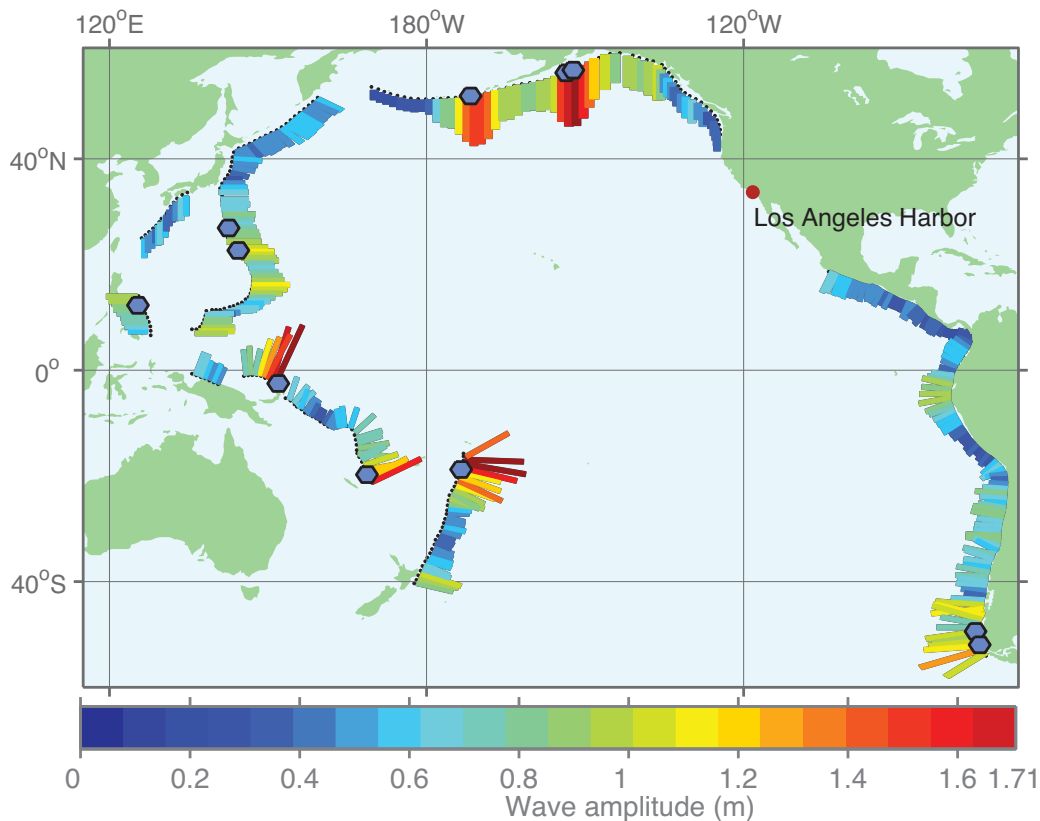

Figure 4.1: The maximum amplitude at the Los Angeles tide gauge from tsunamis triggered by synthetic Mw 9.3 earthquakes along subduction zones around the Pacific Basin as modeled with the Los Angeles tsunami forecast model.

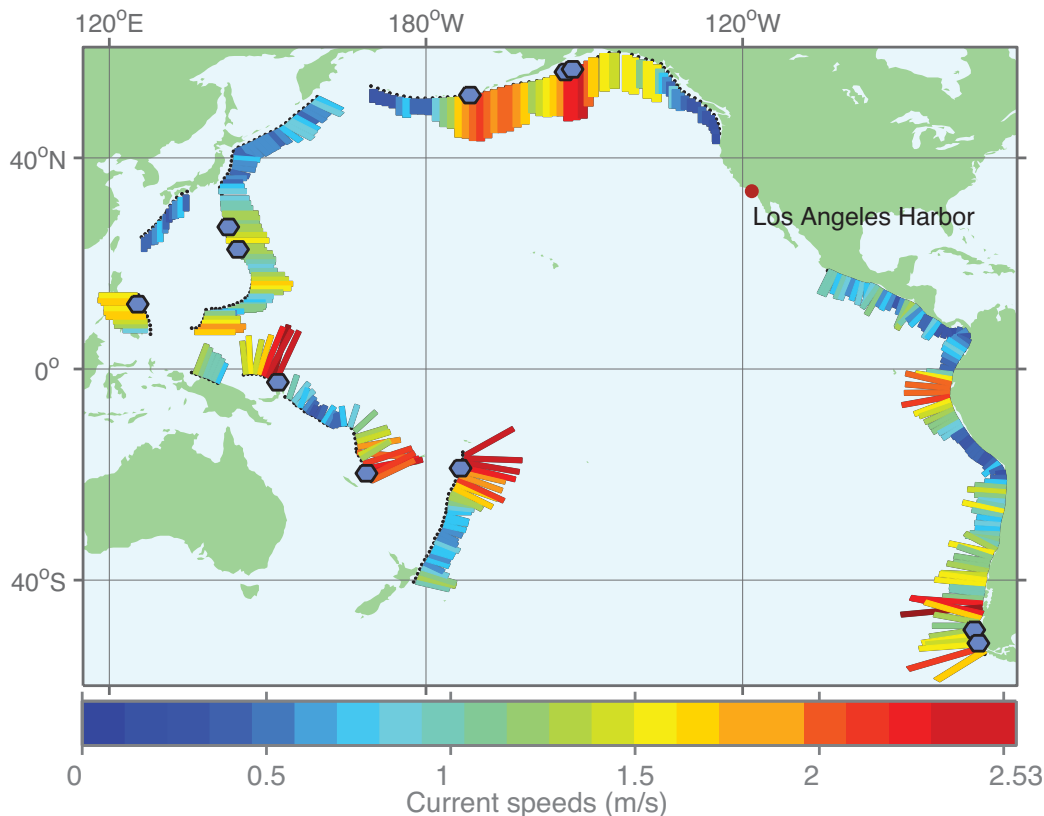

Figure 4.2: The maximum current velocities at the Los Angeles tide gauge, in meters/sec, from tsunamis triggered by synthetic Mw 9.3 earthquakes along subduction zones around the Pacific Basin as modeled with the Los Angeles tsunami forecast model.

Alaska/Aleutians, Manus, Tonga, and South America. The maximum computed wave amplitude is 1.7 m (≈ 5.5 ft) from an Alaska/Aleutian source. Waves exceeding 1 m (3.25 ft) are produced from sources in South America, Manus, New Britain/Vanuatu, and New Zealand/Tonga. There are isolated source locations around the Pacific for which large amplitudes are noted, but Alaska/Aleutian sources consistently return large computed amplitudes at the Los Angeles tide gauge warning point. Kamchatka, Alaska, and Chile can produce Mw 9.+ earthquakes, but the potential for Mariana, Manus, and Tonga subduction zones to produce such a great earthquake is questionable. Overall, tsunami waves larger than 1 m (3.25 ft) at the tide gauge are expected in the event of tsunami generation due to a great, far-field earthquake. In addition, computed maximum wave height and current speed results suggest that the Los Angeles tide gauge is located in a protected portion of the harbor, so amplitudes recorded by this gauge are not representative of other harbor locations and, most importantly, underestimate amplitudes expected elsewhere in the harbor. Predicted tsunami amplitudes on the order of 1 m (3.25 ft) at the tide gauge would likely translate to larger amplitudes expected at other harbor locations.

Current velocities computed at the Los Angeles tide gauge for a total of 322 synthetically generated tsunami source scenarios around the Pacific Basin for

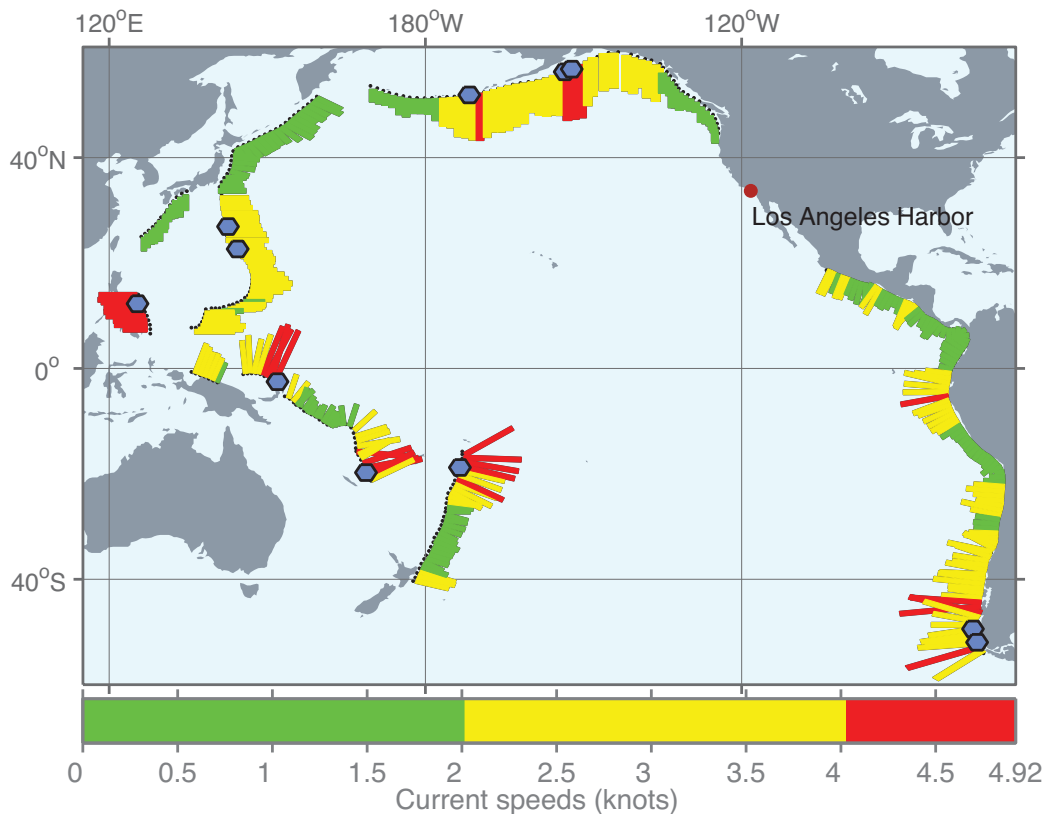

Figure 4.3: The maximum current velocities at the Los Angeles tide gauge, in knots, from tsunamis triggered by synthetic Mw 9.3 earthquakes along subduction zones around the Pacific Basin as modeled with the Los Angeles tsunami forecast model.

a Mw 9.3 earthquake are shown in **Figure 4.2**. For convenience of interpretation, current velocities are presented in m/s as well as in knots in **Figures 4.2 and 4.3**, respectively. Currents in **Figure 4.3** are categorized into three empirical groups: green represents the least risk, corresponding to less than 2 knots; yellow identifies currents in the range of 2–4 knots; and red is reserved for currents in excess of 4 knots, which are considered dangerous. Currents in this red category are computed from sources in the Philippines, Manus, New Guinea, Tonga, Chile, and Alaska/Aleutians. A Mw 9.3 Alaska/Aleutians source resulted in 4.9 knots (≈ 2.53 m/s) at the Los Angeles tide station. Maximum calculated current velocities presented here are revised upward in the following discussion of possible worst-case scenarios.

A comparison of the maximum amplitude results with those of current velocities shows that the greatest qualitative difference is found in distribution. The numerical model results show that even though a few scenarios have big amplitudes at the tide gauge, the scenarios from neighbor segments are relatively smaller. However, in the numerical model a wider distribution with similar currents is observed. This suggests that an earthquake from a similar region is more likely to have similar impacts and be less sensitive to segments in terms of currents than wave amplitudes.

Table 4.1: The list of 11 tsunami sources considered for potential worst-case scenarios at the ports of Los Angeles and Long Beach used in high-resolution simulations from earthquakes triggered by a rupture of a 30-m horizontal slip over an area of 1000 km × 100 km.

Scenarios	Subduction Zone	Tsunami Source
ACSZ 15–24	Alaska-Aleutians-Cascadia	A15–24, B15–24
ACSZ 28–37	Alaska-Aleutians-Cascadia	A28–37, B28–37
ACSZ 29–38	Alaska-Aleutians-Cascadia	A29–38, B29–38

4.2 Potential worst-case scenarios

Based on an examination of the results obtained from all 322 synthetic case scenarios computed, 11 synthetic scenarios, shown as pentagons in **Figures 4.1, 4.2, and 4.3**, are identified as posing a significant risk to the ports of Los Angeles and Long Beach and, therefore, represent possible worst-case scenarios. These scenarios are specific to Alaska, Chile, Philippines, Manus, New Zealand, and Vanuatu. In **Figure 4.4**, both a high-resolution reference model and an optimized tsunami forecast model time series at the Los Angeles tide gauge are shown to be consistent with one another. Even though the maximum computed wave amplitude is from Manus Trench, tsunamis originating from Alaska, South America, Tonga, and Vanuatu produce similar amplitude waves in the ports. This result lends further credibility to the validity of the forecast model and the appropriateness of its use under time constraints.

The high-resolution results, as presented in Appendix B, suggest that a tsunami triggered by a Mw 9.3 earthquake in the Alaska/Aleutians does not necessarily impact the same region in the ports of Los Angeles and Long Beach as a tsunami triggered by a Mw 9.3 earthquake in Kamchatka or the Philippines. Because of the directivity of the waves, they have different impact zones in the harbors, and this may mislead port and emergency managers during future events. In addition, consideration should be paid to the relative location of the tide gauge used as a warning point in this study. Model results at this site are not necessarily the maximum in the ports, suggesting that larger waves could occur in other port regions than those predicted or observed at the tide gauge location.

4.3 A potential tsunami from Alaska

The results of this study suggest that tsunamis generated in Manus, Vanuatu, Tonga, South America, and Alaska-Aleutian-Cascadia subduction zones can be

Figure 4.4: Comparison of the time series of the different synthetic tsunami events for the ports of Los Angeles and Long Beach, California, from high-resolution model (red) and forecast model (green). Sources are given in the left-hand side of each time series.

Figure 4.5: Maximum wave amplitudes (a) and currents (b) at the ports of Los Angeles and Long Beach from the synthetic tsunami ACSZ 29. The figure is represented in larger scale in Appendix B as **Figures B.5 and B.6**, together with the results from the rest of the synthetic scenarios.

potentially dangerous to the ports of Los Angeles and Long Beach. No historical data for Mw 9.3 earthquakes originating along Manus, Vanuatu, and Tonga are available. The likeliest potential worst-case candidate tsunami, however, is not expected from these source regions, but is instead expected to be generated by an earthquake from the Alaska-Aleutian-Cascadia subduction zone. Propagation database segments 29–38 are combined for the worst-case tsunami source. The maximum expected wave amplitudes and current velocities from this source are shown in **Figure 4.5**, and are also presented in larger scale in Appendix B, B.5, and B.6. Based on the results shown in **Figure 4.5**, a Mw 9.3 earthquake from Alaska will potentially trigger a tsunami capable of producing

wave amplitudes up to 2 m (≈ 6.5 ft) and current velocities exceeding 4 m/s (≈ 8 knots) in the ports of Los Angeles and Long Beach.

5. Conclusion

Tsunami waves propagate in a complex and highly directional pattern away from the source region of generation. Propagation and wave energy patterns reflect bathymetry encountered by tsunami waves as they transit the ocean basins. The location of tsunami generation and bathymetry between the source and a given harbor might result in one source posing a significantly greater danger than another source, even though they are within close proximity of one another. Seismic characteristics and faulting mechanisms also play an important role in the impact potential that a generated tsunami poses to coastal communities. Studies have shown that tsunamis triggered by similar magnitude earthquakes from different subduction zones may result in substantially different impact at the same harbor.

The southern California region, including the ports of Los Angeles and Long Beach, has a well-documented seismic history. For this reason, a detailed hazard assessment has been conducted for the ports of Los Angeles and Long Beach. Of 322 synthetic scenarios investigated in this study, 11 source regions in Alaska, Chile, Philippines, Manus, New Zealand, and Vanuatu are identified

Table 5.1: Summary of range of likely travel times from sources to the ports computed for each subduction zone to the Los Angeles tide station. Earliest and latest arrival times are provided.

Subduction Zone	Time (hr)	Tsunami Source	Computed Amplitude the Tide Station
<i>Earliest Expected Arrival</i>			
Alaska-Aleutians-Cascadia	2 hr 15 min 56 sec	ACSZ 56–65	46 (cm)
Central and South America	3 hr 40 min 25 sec	CSSZ 1–10	69 (cm)
East Philippines	14 hr 51 min 26 sec	EPSZ 9–18	90 (cm)
Kuril-Kamchatka-Japan	9 hr 2 min 29 sec	KISZ 1–10	56 (cm)
Manus OCB	13 hr 53 min 42 sec	MOSZ 1–10	176 (cm)
North New Guinea	14 hr 55 min 31 sec	NGSZ 2–11	58 (cm)
New Zealand-Kermadec-Tonga	10 hr 50 min 21 sec	NTSZ 27–36	152 (cm)
New Britain-Solomons-Vanuatu	12 hr 41 min 20 sec	NVSZ 16–25	63 (cm)
Ryukus-Kyushu-Nankai	12 hr 38 min 38 sec	RNSZ 13–22	58 (cm)
<i>Latest Expected Arrival</i>			
Alaska-Aleutians-Cascadia	7 hr 46 min 33 sec	ACSZ 1-10	28 (cm)
Central and South America	15hr 30min 21sec	CSSZ 106–115	100 (cm)
East Philippines	15hr 6min 54sec	EPSZ 1–10	57 (cm)
Kuril-Kamchatka-Japan	13hr 53min 49sec	KISZ 66–75	95 (cm)

as having the potential to generate a tsunami significant to the ports of Los Angeles and Long Beach. A summary of range of likely travel times from sources to the ports is presented in **Table 5.1** for each subduction zone to the Los Angeles tide station. The earliest tsunami is detected at the tide gauge in 2 hr 15 min from the Alaska-Aleutians-Cascadia Subduction Zone, the latest is from North New Guinea in 15 hr 1 min. Findings show that tsunamis generated along far-field subduction zones pose considerably more danger to the ports of Los Angeles and Long Beach than previously thought. Far-field source generation of a tsunami from Mw 9.3 earthquakes can potentially impact the two ports with wave amplitudes reaching up to 2 m (≈ 6.5 ft) and currents exceeding 4 m/s (≈ 8 knots). Currents exceeding 2 m/s (≈ 4 knots) are known to break mooring lines and damage harbor piers and other structures. Depending on the magnitude of the earthquake and the initial condition of the source, then, it is recommended that tsunamis from subduction zones in the Alaska/Aleutians, Central and South America, Eastern Philippines, Kuril Islands-Mariana, Manus, New Zealand/Tonga, and New Britain/Vanuatu be assessed immediately following generation. Due to their importance to United States commerce, the hazard posed by tsunamis is of great concern because the potential devastation and impact would likely interrupt commerce, marine, and tourism activities. Tourist attractions, including the Maritime Museum, Aquarium of the Pacific, and *Queen Mary* (**Figure 1.1**), along with the large number of tourists who visit them daily, are potentially at risk.

Appendix A

Glossary

Arrival time The time when the first tsunami wave is observed at a particular location, typically given in local and/or universal time, but also commonly noted in minutes or hours relative to the time of the earthquake.

Bathymetry The measurement of water depth of an undisturbed body of water.

Cascadia Subduction Zone Fault that extends from Cape Mendocino in Northern California northward to mid-Vancouver Island, Canada. The fault marks the convergence boundary where the Juan de Fuca tectonic plate is being subducted under the margin of the North America plate.

Current speed The scalar rate of water motion measured as distance/time.

Current velocity Movement of water expressed as a vector quantity. Velocity is the distance of movement per time coupled with direction of motion.

Digital Elevation Model (DEM) A digital representation of bathymetry or topography based on regional survey data or satellite imagery. Data are arrays of regularly spaced elevations referenced to a map projection of the geographic coordinate system.

Epicenter The point on the surface of the Earth that is directly above the focus of an earthquake.

Focus The point beneath the surface of the earth where a rupture or energy release occurs due to a buildup of stress or the movement of Earth's tectonic plates relative to one another.

Inundation The horizontal inland extent of land that a tsunami penetrates, generally measured perpendicularly to a shoreline.

Marigram Tide gauge recording of wave level as a function of time at a particular location. The instrument used for recording is termed a marigraph.

Method of Splitting Tsunamis (MOST) A suite of numerical simulation codes used to provide estimates of the three processes of tsunami evolution: tsunami generation, propagation, and inundation.

Moment Magnitude (M_w) The magnitude of an earthquake on a logarithmic scale in terms of the energy released. Moment magnitude is based on the size and characteristics of a fault rupture as determined from long-period seismic waves.

- Near-field** A particular location at which the Earth's deformation due to energy release affects the modeling solution.
- Propagation database** A basin-wide database of pre-computed water elevations and flow velocities at uniformly spaced grid points throughout the world oceans. Values are computed from tsunamis generated by earthquakes with a fault rupture at any one of discrete 100×50 km unit sources along worldwide subduction zones.
- Runup** Vertical difference between the elevation of tsunami inundation and the sea level at the time of a tsunami. Runup is the elevation of the highest point of land inundated by a tsunami as measured relative to a stated datum, such as mean sea level.
- Short-term Inundation Forecasting for Tsunamis (SIFT)** A tsunami forecast system that integrates tsunami observations in the deep-ocean with numerical models to provide an estimate of tsunami wave arrival and amplitude at specific coastal locations while a tsunami propagates across an ocean basin.
- Subduction zone** A submarine region of the Earth's crust at which two or more tectonic plates converge to cause one plate to sink under another, overriding plate. Subduction zones are regions of high seismic activity.
- Synthetic event** Hypothetical events based on computer simulations or theory of possible or even likely future scenarios.
- Tele-tsunami or distant tsunami or far-field tsunami** Most commonly, a tsunami originating from a source greater than 1000 km away from a particular location. In some contexts, a tele-tsunami is one that propagates through deep ocean before reaching a particular location without regard to distance separation.
- Tidal wave** Term frequently used incorrectly as a synonym for tsunami. A tsunami is unrelated to the predictable periodic rise and fall of sea level due to the gravitational attractions of the moon and sun: the tide.
- Tide** The predictable rise and fall of a body of water (ocean, sea, bay, etc.) due to the gravitational attractions of the moon and sun.
- Tide gauge** An instrument for measuring the rise and fall of a column of water over time at a particular location.
- Travel time** The time it takes for a tsunami to travel from the generating source to a particular location.
- tsunami** A Japanese term that literally translates to "harbor wave." Tsunamis are a series of long-period shallow water waves that are generated by the sudden displacement of water due to subsea disturbances such as earthquakes, submarine landslides, or volcanic eruptions. Less commonly, meteoric impact to the ocean or meteorological forcing can generate a tsunami.

Tsunami Hazard Assessment A systematic investigation of seismically active regions of the world oceans to determine their potential tsunami impact at a particular location. Numerical models are typically used to characterize tsunami generation, propagation, and inundation, and to quantify the risk posed to a particular community from tsunamis generated in each source region investigated.

Tsunami Propagation The directional movement of a tsunami wave outward from the source of generation. The speed at which a tsunami propagates depends on the depth of the water column in which the wave is traveling. Tsunamis travel at a speed of 700 km/hr (450 mi/hr) over the average depth of 4000 m in the open deep Pacific Ocean.

Tsunami source Location of tsunami origin, most typically an underwater earthquake epicenter. Tsunamis are also generated by submarine landslides, underwater volcanic eruptions, or, less commonly, by meteoric impact of the ocean.

Wave amplitude The maximum vertical rise or drop of a column of water as measured from wave crest (peak) or trough to a defined mean water level state.

Wave crest or peak The highest part of a wave or maximum rise above a defined mean water level state, such as mean lower low water.

Wave height The vertical difference between the highest part of a specific wave (crest) and its corresponding lowest point (trough).

Wavelength The horizontal distance between two successive wave crests or troughs.

Wave period The length of time between the passage of two successive wave crests or troughs as measured at a fixed location.

Wave trough The lowest part of a wave or the maximum drop below a defined mean water level state, such as mean lower low water.
