The National Ocean Service (NOS) Center for Operational Oceanographic Products and Services (CO-OPS) provides the National infrastructure, science, and technical expertise to collect and distribute observations and predictions of water levels and currents to ensure safe, efficient and environmentally sound maritime commerce. The Center provides the set of water level and tidal current products required to support NOS' Strategic Plan mission requirements, and to assist in providing operational oceanographic data/products required by NOAA's other Strategic Plan themes. For example, CO-OPS provides data and products required by the National Weather Service to meet its flood and tsunami warning responsibilities. The Center manages the National Water Level Observation Network (NWLON), a national network of Physical Oceanographic Real-Time Systems (PORTS®) in major U. S. harbors, and the National Current Observation Program consisting of current surveys in near shore and coastal areas utilizing bottom mounted platforms, subsurface buoys, horizontal sensors and quick response real time buoys. The Center: establishes standards for the collection and processing of water level and current data; collects and documents user requirements which serve as the foundation for all resulting program activities; designs new and/or improved oceanographic observing systems; designs software to improve CO-OPS' data processing capabilities; maintains and operates oceanographic observing systems; performs operational data analysis/quality control; and produces/disseminates oceanographic products.

EXECUTIVE SUMMARY

Extreme monthly highest and lowest water levels at 112 long-term stations of the National Water Level Observation Network (NWLON) operated by the Center for Operational Oceanographic Products and Services (CO-OPS) are analyzed to quantify probabilities of exceedance and the return periods of extreme events. All data through 2010 are used from stations on the U.S. Atlantic and Pacific coasts, the Gulf of Mexico, Hawaii, Alaska, and islands in the Pacific and Atlantic Oceans. Since there are statistically significant trends in the data, the values are linearly detrended using the mean sea level trend (or the mean high or low water trend in a few cases) prior to analysis. A set of the annual maxima and annual minima are then derived for each station.

The Generalized Extreme Value (GEV) approach was chosen to characterize the distribution of extreme values of a long-term water level time series. A GEV distribution is fitted to each station's annual maxima or minima by solving for the location, scale, and shape parameters. The solution defines an exceedance probability curve and its 95% confidence interval as a function of the return period, which is the average length of time between exceedances of a given extreme water level.

The shapes of the derived GEV curves show large variations at the longer return periods depending on whether the GEV shape parameter is positive (the curve rises sharply) or negative (the curve flattens out). A positive shape parameter indicates a distribution with a higher probability of a rare event in the extreme tail of the distribution. A GEV curve with a positive shape parameter also has much wider 95% confidence intervals than one with a negative shape parameter. The stations with occasional large hurricane storm tides in the data generally have positive shape parameters. Stations on coasts that do not experience hurricanes generally have GEV curves which flatten out at longer return periods and have narrow 95% confidence intervals at the longer return periods.

In the Appendices, the GEV exceedance levels for each station are displayed as a set of plots showing their relationship with the observed annual maxima or minima versus return period, with the tidal and geodetic datums as a stick diagram relative to mean sea level, and with the observed monthly highest and lowest water levels versus time. Extreme events which exceeded the 0.01 exceedance probability level, which can be considered as a 100-year event, are identified. The monthly data are also separated into sets of the highest and the lowest water levels for each month of the year. A GEV analysis is then performed on each of the 24 subsets to show how the likelihood of exceedance changes seasonally.

Hurricane Sandy struck the coast of New Jersey in October 2012. Its peak water level at The Battery was over a meter higher than any previously recorded water level. Levels reached at Bridgeport and Sandy Hook (before the station was destroyed) were also far above previous records. As a result, the GEV exceedance probability levels for high water levels at these three stations were recalculated and the results are discussed in Appendix VIII.

I. Introduction

A. What can be learned from extreme water levels recorded over the past century?

For almost 160 years, coastal water levels in the United States have been measured by continuously-recording instrumentation deployed by the U.S. Coast and Geodetic Survey and its successor agencies. Today, this task is carried out by the Center for Operational Oceanographic Products and Services (CO-OPS) of the National Ocean Service (NOS). The primary reasons that coastal water levels began to be recorded were to derive the harmonic tidal constituents at a particular location for making tide predictions and to collect a sufficient number of observed high and low waters to establish tidal datums for navigational charts, for geodetic surveys, and for legally delineating shorelines and marine boundaries.

Over the years, human "computers" and later electronic computers produced quality-controlled tabulations of hourly (and later six-minute) water levels, and the times and heights of high and low waters. Monthly means were derived from these data sets, including the monthly means of the hourly data (i.e., the monthly mean sea level) and a set of mean tide levels from the high and low waters tabulated for each day, such as the monthly mean high water and mean low water, among others. Also tabulated were the highest and lowest observed water levels for each month, which will form the basis for this NOAA Technical Report.

The establishment of a tidal datum at a primary station requires a 19-year period of observation, known as a tidal datum epoch, to capture the variation caused by the precession of the lunar node (Gill and Schultz, 2001). At other (secondary or tertiary) stations, that are near a primary station and have similar tidal curves, only a year or less of observation is required to establish their tidal datums by a comparison of simultaneous observations (Center for Operational Oceanographic Products and Services, 2003).

Once enough data were collected at a location for tidal prediction and for the establishment of tidal datums, it might be expected that further recording of water levels at a particular location would no longer be required. Fortunately, historical observations were continued at a limited number of primary stations around the nation's coasts in recognition that major changes to harbor configurations and depths, whether natural or man-made, could affect the tides. Therefore, once a 19-year tidal datum epoch was complete and official U.S. tidal datums were established, data continued to be collected at primary stations for the calculation of the next tidal datum epoch.

Originally, the nation-wide network of long-term continuous water level stations (now called the National Water Level Observation Network (NWLON)) was quite small, but has since grown to approximately 210 stations, including, since 1970, stations on the Great Lakes previously operated by the Army Corps of Engineers. Today, these stations provide data for many operational purposes beyond tide predictions and datums. Real-time data collection supports

safe and efficient use of our ports, tsunami warning networks, storm surge modeling, and inundation frequency and duration information.

Over time, it became known that in some parts of the world, particularly in Scandinavia, there are rapid vertical land motions leading to changes in relative sea level that are noticeable over decades or centuries (Marmer, 1951). Sure enough, after several decades of data were collected, it became clear that many U.S. coastal areas had long-term relative sea level trends that are statistically significant (non-zero), due to a combination of vertical land motion and absolute sea level rise (Zervas, 2009). As a result of these long periods of data collection and the tabulation of monthly highest and lowest water levels, records of the most extreme water levels at each station can be placed in a historical context of the more routine highest/lowest water levels observed in most other months.

Many of the analyses, applications, and products that employ the CO-OPS historical water level database are based only on the more recently collected data from the long-term stations. The most commonly-produced analysis that uses a station's entire historical record is the calculation of the mean sea level trend, which is derived from the monthly mean sea levels, often condensed by researchers into a set of annual means. There have also been a few studies that have used entire sets of monthly tide levels to calculate changing tidal ranges in coastal regions ((Flick et al., 2003); Zervas in (Coastal Services Center, 2003)). Bromirski et al. (2003) used the entire series of hourly water levels at San Francisco since 1858, in order to estimate changes in "storminess" from its detided residual time series. A similar study (Zhang et al., 2000) employed ten east coast stations from Portland, ME to Mayport, FL. So far, there have been no comprehensive publications presenting the entire record of monthly highest and lowest water levels at long-term U.S. coastal stations and performing statistical analyses on these data sets.

B. What types of extreme value analysis are carried out in this report?

The monthly highest and lowest water levels were derived from a much greater amount of data (i.e., from six-minute or hourly water levels or even earlier from the direct measurement of analog tide curves recorded on paper). Tsunamis and high-frequency harbor seiches were always excluded from CO-OPS high and low water tabulations by smoothing. The data to be examined are a sampling from a distribution of extreme values from (nearly) equal-length time periods (i.e., monthly maxima and minima). The distribution of extreme values can be fitted by any number of probability distribution formulae. This procedure has been carried out by many researchers and the distribution that fits best is often chosen as the correct distribution and used to estimate extreme value return periods for times greater than the length of the observations. Although many of these distributions were chosen empirically, the theoretically-expected distribution of extremes should follow the Generalized Extreme Value (GEV) distribution (Katz et al., 2002). This is the distribution chosen for this report.

The three GEV parameters (location, scale, and shape) are fitted to the maxima or minima data employing a maximum likelihood estimate (Gilleland and Katz, 2006; Gilleland et al., 2005). Maximum likelihood is a statistical method of solving for the set of model parameters that are the most likely to have produced the observed data. The extRemes package of the R statistical analysis software, developed by the Weather and Climate Impact Assessment Science Program at the National Center for Atmospheric Research (NCAR) (Gilleland et al., 2013; Stephenson and Gilleland, 2005) is used to calculate the GEV parameters.

The analysis is carried out for long-term NWLON stations utilizing all available data through the end of 2010. Since the long-term relative sea level trend at each station can make a substantial difference in how high or low a storm event can reach, depending on whether the event occurred near the beginning, middle, or end of the series, a linear trend is first subtracted from the monthly highest and lowest values. A set of annual highest and lowest values is then produced from the years that have at least four months of data. Years with less than a full year of data are evaluated and dropped if they have a known extreme event missing based on inter-station comparisons.

Once a GEV probability distribution is fitted to the data using a maximum likelihood estimation, a set of plots for each station is produced to clearly demonstrate the results for various practical applications. Exceedance probability level curves are first plotted relative to a range of return periods from 1 year to 200 years. The GEV parameter most important for characterizing the upper tail of the distribution, which includes the most extreme events, is the shape parameter. It is plotted for all stations by region to show similarities and differences between stations.

The levels for the 99%, 50%, 10%, and 1% annual exceedance probabilities are then compared by region to indicate variations of the levels that can be reached and to also identify stations that may have questionable results due to shorter records and/or missing storms. Another set of plots displays each station's stick diagram showing the tidal datums, a geodetic datum (if available), and several high water and low water exceedance probability levels relative to the mean sea level datum (MSL). A third set of plots shows each station's monthly highest or lowest levels before detrending and a set of the calculated exceedance probability levels for several return periods which follow the station's mean sea level trend.

Subsequently, an additional group of GEV analyses are carried out using each station's highest or lowest levels for each of the twelve individual months of the year. These results indicate which months and seasons are most and least likely to have the most extreme storm tide events. The seasonal cycles of the exceedance probability levels for several return periods are plotted for several regionally-representative stations.

C. What applications can use the results of this analysis?

The results presented in this NOAA Technical Report have many practical applications to assist a broad range of users in decision-making and problem solving. Each extreme high or low water event in the historical record can be categorized by its probability of occurrence and return period. Events occurring in the near future will be able to be easily categorized as soon as the water level crosses an exceedance probability threshold. Extreme low waters will be able to be recognized in real time and appropriate navigational warnings could be disseminated to prevent possible ship groundings.

Knowledge of exceedance probability levels will be extremely helpful for coastal planners and managers in their evaluation and assessments of hazards. These levels are critical for most coastal construction projects such as housing, commercial buildings, ports, roads, bridges, sewer/water treatment infrastructure, and storm drainage systems. It is also vitally important for the development of storm surge protection structures and floodplain management.

The Federal Emergency Management Agency (FEMA) bases its coastal flood maps (National Research Council, 2009) on an assessment of the 1% annual probability of inundation level which it calls the Base Flood Elevation (BFE). Their maps also include a zone of 0.2% annual probability of inundation which corresponds to a 1-in-500-year inundation event. The exceedance probability levels calculated in this report are based only on the levels recorded by water level gauges; these levels do not include wave effects which also contribute to the BFEs calculated by FEMA. Water levels measured by gauges correspond more closely to what FEMA defines as the stillwater elevation (SWEL). Although FEMA's definition does not include the wave setup effect, water levels recorded by gauges can include a limited amount of wave setup based on their degree of exposure to ocean waves. FEMA's flood insurance studies (FIS), which are the basis of its flood insurance rate maps (FIRM), employ a number of approaches including extensive numerical modeling with a variety of additional physical effects, but the calculation and/or modeling of SWELs is the underlying basis for flood zoning (Crowell et al., 2007).

Exceedance probability levels are important not just for man-made structures but also for natural ecosystems (Scavia et al., 2002). State and local agencies responsible for management of floodplains and natural coastal landscapes require precise knowledge of land elevations and their relationships to the probability of frequent or infrequent inundation. Coastal marsh ecosystem restoration projects can use this information in their decisions about what types of vegetation will flourish at various land elevations. Beach replenishment and coastal dune restoration projects also require information about exceedance probabilities. These types of projects, which can create or restore a healthy ecosystem, also provide benefits to adjacent developed areas by providing a storm surge and wave buffer.

Once exceedance probability levels are derived, they can be used to project the likelihood of inundation at a location into the future since they are tied to the local tidal datums. They can be raised or lowered by projecting the calculated mean sea level trend into the future. Alternatively,

various scenarios for estimating an acceleration in the rate of global or regional sea level rise, such as those recommended by the Corps of Engineers (Moritz et al., 2012) or by NOAA for the National Climate Assessment (Parris et al., 2012), can be incorporated in projecting future exceedance probability levels (Flick et al., 2013). The implicit underlying assumption would be that there would be no change in storm frequencies in the future.

II. Theory and Methods of Extreme Value Analysis

A. GEV Formulae and Classification

Many different statistical distributions have been employed to describe the frequency of occurrence of extreme values in a time series. Data are either a series of maximum values occurring in equal time blocks such as days, months, or years or all the values above a chosen extreme threshold. A number of different analytical functions are fitted to the data and the best-fitting function is often chosen to represent the extreme value distribution. The US Geological Survey (USGS), for example, has chosen the Log-Pearson Type III probability distribution function as the basis for its calculation of river flood frequencies based on empirical evidence that it give the best results, where the data used are the logarithm of the annual maximum stream flows (Stedinger and Griffis, 2008; Water Resources Council Hydrology Committee., 1981).

The use of one specific family of probability distribution functions for extreme values can be mathematically justified on a theoretical basis (Coles, 2001). For block maxima data, the Generalized Extreme Value (GEV) functions are the appropriate distributions to use, whereas for peaks-over-threshold (POT) values, the Generalized Pareto Distribution (GPD) functions are preferred. The GEV distribution is completely described by three parameters, known as the location, scale, and shape parameters. The GPD is also completely described by three parameters: the chosen threshold, the scale parameter (which is threshold-dependent), and the shape parameter (which is not). The GEV and GPD are related distributions; either distribution's parameters can be expressed in terms of the other distribution's parameters and they both have the identical shape parameter.

In this report, the GEV distribution function will be applied to block maxima and block minima data. This approach is chosen because CO-OPS has a complete database of the monthly highest and lowest water levels for many long-term water level stations. The GPD approach would require using the high/low waters or the hourly data; however, the digitized record is incomplete for many long-term stations. The daily high /low water data (e.g., two high waters and two low waters per day at semidiurnal tidal stations) are in the digitized database only since the mid-1970s. There are nearly complete long-term digitized hourly data for some of the long-term stations in the database, but not for others. Leaving out any of the most extreme events early in the historical record can have a large effect on the results for the longer return periods. The GPD approach also requires selection of a different threshold for each station. A complete GPD analysis of these stations, however, would be a useful follow-up study to this report.

The GEV cumulative distribution function F as a function of a parameter x, such as the water level height, can be written as

$F(x; \mu, \sigma, \xi) = \exp \{ - [1 + \xi(x-\mu)/\sigma]^{-1/\xi} \}$ for $- \infty < x \leq \mu - (\sigma/\xi)$, when $\xi < 0$ (Weibull)

$F(x; \mu, \sigma) = \exp \{ - \exp [- (x-\mu)/\sigma] \}$ for $- \infty < x < + \infty$, when $\xi = 0$ (Gumbel)

$F(x; \mu, \sigma, \xi) = \exp \{ - [1 + \xi(x-\mu)/\sigma]^{-1/\xi} \}$ for $\mu - (\sigma/ \xi) \leq x < + \infty$, when $\xi > 0$ (Fréchet)

where μ, σ, and ξ are the location, scale, and shape parameters of the distribution. The probability distribution functions (shown in Figure 1) can be derived by taking the derivative of F with respect to x. For $\xi < 0$, the distribution is called the Weibull distribution; for $\xi = 0$, it is called the Gumbel distribution; and for $\xi > 0$, it is called the Fréchet distribution. The Weibull distribution has the smaller probability of including a value much larger than μ; in fact, it goes to zero above x = 5 in the example in Figure 1. The Gumbel distribution, extends from $-\infty$ to $+\infty$, and is sometimes known as a light-tailed distribution. The Fréchet distribution, which is zero below x = -5 in the example in Figure 1 and extends to $+\infty$, is sometimes known as a heavy-tailed distribution because it has a higher probability of a value much larger than μ occurring.

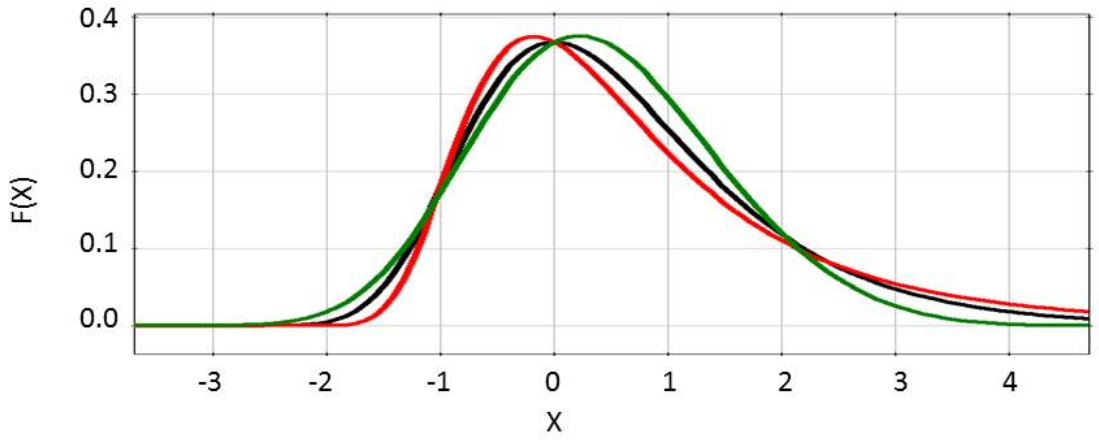

Figure 1. Generalized Extreme Value (GEV) probability distribution functions with a location parameter of 0 and a scale parameter of 1. The shape parameters are -0.2 for the green curve (Weibull distribution), 0 for the black curve (Gumbel distribution), and 0.2 for the red curve (Fréchet distribution).

B. Approach to Deriving GEV Parameters and the Analysis Software Employed

Preliminary plots of monthly highest and lowest water levels show that there is an obvious long-term linear trend in the data at most stations. This linear trend is very close to the corresponding long-term trend in the station's mean sea level. In this report, mean sea level trends, based on data up to 2006 (Zervas, 2009), are adopted as the baseline rate of change affecting the monthly highest and lowest water levels. At a few of the stations, a different rate and an offset were calculated before and after an earthquake; monthly highest and lowest levels are assumed to also follow these abrupt changes in mean sea level. At four stations, it is evident that the monthly highest and lowest water levels have differing baseline rates of change. Significantly different rates for mean high and low waters have been calculated at these stations (Zervas in (Coastal Services Center, 2003)), reflecting continual increases in their tidal range, possibly due to the hydrodynamic response of these harbors to the deepening of their navigational channels. At

these stations, updated rates for mean high and low waters are calculated for this report and used as the baseline rates of change for the monthly highest and lowest water levels.

Since the basis of the extreme value theory is that each observed level will be assigned a calculated probability of exceedance, which should be independent of when it appears in the series, the monthly highest and lowest water levels are first detrended to remove the time dependence of the values before the GEV analysis is carried out. This is accomplished by removing a line with the mean sea level trend crossing zero at the mid-point of the National Tidal Datum Epoch of 1983-2001 which is 1992.5. Some of the stations in Louisiana, Texas, and Alaska, which have larger rates of sea level change, are on more recent 5-year modified tidal datum epochs (MTDE); for these stations, the line removed crosses zero at the mid-point of these 5-year periods. An alternate approach would be to solve for the mean trend as an additional non-stationary parameter in the analysis of extreme water levels (Menendez and Woodworth, 2010).

There will be two types of GEV analysis in this report: one of the annual extreme values for each station, and then twenty four separate analyses using the high and low extreme values for each individual month for each station. The annual extreme values are derived for each year having at least four months of data. Then a review of each annual extreme value data set is carried out to see if, for partial years, there are values that are definitely not the annual extreme value, due to a regular seasonal cycle at the station; these annual extremes are removed. The years with less than four months of extreme values are also examined to determine if one of those months clearly had the extreme event of that year; if so, that value is added back to the annual extreme value data set.

The GEV analyses will be carried out using the extRemes package of the R statistical analysis software (Gilleland et al., 2005) developed by the Weather and Climate Impact Assessment Science Program of the National Center for Atmospheric Research (NCAR). The solution is the maximum-likelihood estimate (MLE) derived by an iterative process. The results of each analysis are the three extreme value distribution parameters (μ, σ, ξ) for location, scale, and shape. From these parameters, the extRemes package can compute levels on the exceedance probability curve for any set of requested return periods. Exceedance probability levels are calculated for a range of return periods from 1 year to 200 years. An upper and lower 95% confidence level is also calculated for each return period using the profile-likelihood method. The 95% confidence intervals are not symmetric about the exceedance curve.

III. Water Level Data

A. Selection of Stations

The 112 NWLON long-term water level stations analyzed in this report are listed in Table 1 which gives the station number, latitude, longitude, first year of data, last year of data, year range, station name, and state or territory. Some of the stations analyzed are not presently in operation. These stations and their last year of data are Johnston Atoll (2003), Chuuk (1995), Seavey Island (2001), Port Jefferson (1992), Colonial Beach (2003), Gloucester Point (2003), Portsmouth (1987), Miami Beach (1981), Eugene Island (1974), Port Mansfield (1997), Padre Island (1994), Newport Beach (1993), and Rincon Island (1990).

All the stations had over 30 years of data except for Rincon Island and Nikiski, which had 27 and 26 years, respectively. Their analysis results were judged to be good when compared to neighboring stations so they are included in this report. Two additional stations were initially part of the analysis, Apalachicola (8728690) and Panama City (8729108), but their results were judged to be problematic, despite using 43 and 38 years of data, respectively. These two stations are therefore not included in this report.

Occasionally, various circumstances required the permanent or temporary relocation of an NWLON station. If the old and new stations are in the same vicinity and their levels can be connected to some common tidal bench marks, the old station's series can be continued at the new location assuming no difference in vertical land motion or long-term oceanographic variability between the two sites. It is also implicitly assumed that storm surge amplitudes at the two stations are essentially equivalent.

At the stations listed in Table 2, data from two or more locations were combined to form longer time series. Sometimes, the two stations were operated in tandem for a period to confirm the similarity of their tidal signals. In other cases, such as when a pier was destroyed in a storm, collecting a period of overlapping data was not possible. All of the stations that were combined were placed on a common datum on the basis of a direct leveling connection to common bench marks except for the Willets Point / Kings Point, NY series. These two stations were simultaneously in operation from November 1998 to December 2000 and had nearly identical hourly time series, so it was decided to combine them, making the assumption that there is no mean sea level or tidal difference between them.

The monthly highest and lowest data to be analyzed were the values above the mean higher high water (MHHW) datum for the highest monthly water levels and the values below the mean lower low water (MLLW) datum for the lowest monthly water levels, except at Port Mansfield (8778490). Port Mansfield is located on a coastal lagoon of the Texas coast and has very weak tides; thus it is not possible to establish any tidal datums other than MSL. Therefore, Port Mansfield's monthly highest and lowest water levels relative to MSL were used in the GEV analysis.

The MHHW and MLLW datums at most of the stations are the values officially established by CO-OPS for the National Tidal Datum Epoch (NTDE), a 19-year period during which the tidal cycle caused by the precession of the moon's node is averaged out (Gill and Schultz, 2001). The present-day NTDE is 1983-2001. At Eugene Island (8764311), no data were collected during the 1983-2001 epoch, so the MHHW and MLLW datums used in this report are from the previous 1960-1978 NTDE.

At a limited number of stations in Louisiana, Texas, and Alaska with large mean sea level trends, CO-OPS has introduced 5-year modified tidal datum epochs (MTDE) by adjusting the tidal datums to the height of MSL averaged over a more recent 5-year period. Sabine Pass, Galveston Pier 21, Galveston Pleasure Pier, Freeport, Anchorage, and Unalaska are on the 1997-2001 MDTE. Grand Isle, Rockport, Juneau, Skagway, Yakutat, Seldovia, Nikiski, and Kodiak Island are on the 2002-2006 MTDE.

Table 1. Long-Term Water Level Stations
Some series are a combination of data from two station numbers.
Some stations have separate pre- and post-earthquake trends calculated.

Station Number	Latitude	Longitude	First Year	Last Year	MSL Trend (mm/yr) +/- 95% Conf. Int.		Station Name	State or Territory
1611400	21.955	-159.357	1954	2010	1.53	0.59	Nawiliwili	Hawaii
1612340	21.307	-157.867	1905	2010	1.50	0.25	Honolulu	Hawaii

B. Data Quality Control, Missing Extreme Storms, and High Water Marks

Extensive quality control was carried out on the monthly highest and lowest water level data sets to correct errors in the database and to ensure that the data was as comprehensive and complete as possible. This was accomplished by careful comparisons of the extreme event levels recorded at one station with those recorded at nearby stations. In the process, it was important to distinguish between water levels measured by a gauge and water levels that were inferred because of missing data or placed in the data set from other sources such as a nearby high water mark (HWM) leveled to the tidal bench marks. It was also important to indicate which extreme events that could have been recorded are missing due to the destruction of the station or malfunctioning of the instrument. In some cases, the peak water level of an extreme event was not recorded, so as an attempt to include the event, the last recorded level was included in the data set. Table 3 is a listing of the monthly highest and lowest water levels not directly recorded instrumentally.

C. Detrending of Monthly Highest and Lowest Water Levels

The monthly mean highest and lowest water levels at most stations clearly include an underlying linear trend which reflects the direction of the MSL trend of the station. Where the MSL trend is positive, the highest and lowest water levels are also rising; when the MSL trend is negative, the highest and lowest water levels are also falling. This is because the daily high and low tide levels are also following the MSL trend and many of the monthly highest and lowest water levels are simply the highest and lowest predicted tide of the month, if there is no meteorological event occurring. The presence of the underlying trend affects the level reached by each event in the record. If an event occurs early or late in the time series, it will reach higher or lower than if it had occurred in the middle of the series. In order to evaluate the probability of occurrence of each level with a GEV analysis, all the times series are first detrended. An alternative approach is to allow for a trend in the data and parameterize the GEV analysis to also solve for the value of that trend (Menendez and Woodworth, 2010).

In this report, the time series are detrended with the trends listed in Table 1. For most of the stations, the data are detrended to the time origin (or zero time) of 1992.5, which is the mid-point of the present-day NTDE. For the stations on a 5-year MTDE, the data are detrended to the time origin of 1999.5 or 2004.5, depending on which 5-year MTDE is in use for each station (1997-2001 or 2002-2006). The Eugene Island data are on the 1960-1978 NTDE, so its data are detrended to the time origin of 1969.5.

There are four long-term stations which have been determined to have had significantly increasing tidal ranges over their period of record (Zervas in (Coastal Services Center, 2003)). At these stations (Philadelphia, Beaufort, Wilmington, and Anchorage), the monthly highest water level follows the MHW linear trend and the monthly lowest water level follows the MLW linear trend. The reason that MHW and MLW trends are used instead of MHHW and MLLW trends, is because MHHWs and MLLWs were not tabulated for east coast stations by CO-OPS until the 1970s. The MHW and MLW trends were recalculated with data up to 2011 (Table 4), and used to detrend the monthly highest and lowest values for these four stations.

Table 4. Mean High Water and Mean Low Water Trends for data up to 2011

Station Number	Station Name	MHW Trend (mm/yr)	MLW Trend (mm/yr)
8545240	Philadelphia	4.41 +/- 0.24	0.95 +/- 0.23
8656483	Beaufort	3.77 +/- 0.41	1.54 +/- 0.44
8658120	Wilmington	3.94 +/- 0.35	-0.91 +/- 0.45
9455920	Anchorage	1.38 +/- 0.94	-5.19 +/- 1.40

Three earthquakes which occurred in March 1957 in the Aleutian Islands, March 1964 in southern Alaska, and August 1993 near Guam resulted in discernible offsets and/or changes in

trend at nearby water level stations (Zervas, 2009). At Guam, separate mean sea level trends are calculated before and after August 1993 event. At Seward and Kodiak Island, there are large offsets (> 1 meter) at the time of the March 1964 earthquake; since such a large change in the surrounding bathymetry near these stations could have affected the tides and the local response to storm surges, it was decided not the include any pre-1964 data in the GEV analyses for those two stations. At Adak Island and Unalaska, separate trends were calculated before and after the March 1957 earthquake.

At three Alaskan stations (Yakutat, Cordova, and Valdez), there appears to have been a change in trend between the start and the end of their time series, but it is not clear if the change has been gradual over recent decades (perhaps due to the melting of glaciers) or if it is related to one or more of the nearby large earthquakes that have occurred over the past 50 years. To remove the time-dependent effect of the changing mean sea level on monthly highest or lowest levels, it doesn't make a great difference whether a single theoretical curve or two linear segments are removed. It was decided to remove two separate trends calculated before and after an earthquake in February 1979.

At Freeport (8772440), there is an unexplained datum shift in January 1972 in the monthly mean sea level series (Zervas, 2009), so the monthly highest and lowest values for Freeport were detrended incorporating the apparent datum shift with the same linear trend before and after January 1972.

D. Generation of Monthly and Annual Extreme Data Sets

The detrended monthly and annual highest and lowest water levels comprise the data sets that are used for the GEV analyses in this report. Each station's GEV annual exceedance probability curve is derived by a maximum likelihood estimate using the extRemes package of the R statistical analysis software. Therefore, annual extreme values are first obtained from the detrended monthly extremes data set; however, if a year has less than four months of monthly values, no annual maxima or minima are supplied to the station's annual extremes data set.

Three exceptions are made for years in which there are less than four months of data, where a monthly extreme is clearly the extreme value for the year: the February 1972 high water level for Montauk, the March 1993 high water level for Clearwater Beach, and the January 1997 low water level for Cherry Point. In three other instances, there are four or more months of data, but the annual maxima or minima is clearly in one of the missing months; therefore, that year is deleted from that station's annual extremes data set. These years are: 1979 for the annual highest water level for Anchorage, 1975 for the annual lowest water level for Apalachicola, and 1966 for the annual lowest water level for Kodiak Island.

The monthly highest and lowest water levels are also used to produce a set of twenty four GEV analyses, two for each month, to show how the high and low water exceedance probability levels

can vary month by month, over the course of a year. To do this, the monthly highest and lowest water levels are separated into twenty four data sets, one each for the high and the low extreme values recorded in each month of the year.

IV. Analysis and Discussion

A. Annual GEV Curves and Shape Parameters

The result of a GEV analysis consists of the three parameters for location, scale, and shape, including the standard error of each parameter. The 95% confidence intervals are obtained by multiplying the standard errors by 1.96. The GEV parameters are listed in Appendix I and II for all the stations. Table A in Appendix I gives the parameters for annual highest water levels and Table B in Appendix II gives the parameters for annual lowest water levels.

The location parameter is a measure, roughly comparable to a mean or a median, of how far above MHHW or below MLLW the annual highest or lowest water levels tend to be. The scale parameter is a measure, generally comparable to the standard deviation of a normal distribution, of how variable the annual highest or lowest water levels can be from year to year. The shape parameter, which is non-dimensional, represents how skewed the GEV distribution is, and is important in quantifying the occurrence of values far more extreme than the location parameter. An extreme value far exceeding the location parameter (i.e., in the upper tail of the distribution) is statistically more likely when the shape parameter is positive and less likely when the shape parameter is negative.

The GEV parameters define a curve of annual exceedance probability levels customarily shown with 95% confidence intervals as a function of the return period, also known as the average recurrence interval. By calculating these levels for a range of exceedance probabilities from 99% to 0.5% (equivalent to return periods of 1.01 to 200 years), the exceedance probability curves are generated and plotted in Appendix I and II for the highest and lowest annual extreme water levels. The return periods of 1.01, 2, 10, and 100 years, corresponding to exceedance probabilities of 99%, 50%, 10%, and 1%, are labeled on the plots. The 10% and 1% annual exceedance probability levels are the levels that are exceeded on average 10 times and 1 time, respectively, per century. The 50% annual exceedance probability level is actually the median of the annual water level maxima or minima, i.e., in half of the years the annual maximum or minimum is higher and in the other half the annual maximum or minimum is lower. The 99% annual exceedance probability defines the level that is not exceeded in only one year out of every 100 years on average. That does not mean that it cannot be exceeded multiple times in other years.

The data values used in the derivation of the curves (i.e., the annual extreme water levels), are also plotted on the figures in Appendix I and II as dots in their Weibull plotting positions as a function of the return period in years (Water Resources Council Hydrology Committee., 1981), which is defined as

$$(N+1) / r$$

where N is the number of annual extreme values and r is the integer ranking of the level from most extreme (r = 1) to least extreme (r = N). There are other theoretical plotting positions that are sometimes used, which plot the most extreme values (r = 1, 2, 3, …) somewhat further to the right at longer return periods. The plotting positions chosen for the figures have no bearing on the calculation of the GEV curves. The discussion below of the stations' shape parameters in Figures 2 to 7 can be best understood by referring to the exceedance probability curves in Appendix I and II to see the effect of differing shape parameters at the longer return periods (Gilleland and Katz, 2006).

The East Coast high water shape parameters (Figure 2) are mostly positive (Fréchet distributions—see Section II.A) although most of their 95% confidence intervals also include zero (Gumbel distributions). The most extreme events in the Gulf of Maine (Eastport to Boston) are winter storms; for the rest of the East Coast, the extreme events are a mix of winter storms and hurricanes, with the most extreme event more likely to be a hurricane. The few stations with slightly negative shape parameters (Weibull distributions) have 95% confidence intervals which also overlap zero (Gumbel distributions), and generally have a shorter period of record for the GEV calculation than neighboring stations. Therefore, they may not include an older extreme event that might have been recorded if the station had been in operation at the time and which could have made its shape parameter positive. Washington has the most positive shape parameter because its record of extremes is greatly influenced by several large river floods, unlike any of the records at other stations.

The West Coast high water shape parameters (Figure 3) are mostly negative with only a few of the 95% confidence intervals at the stations with short periods of record also including zero. The most negative shape parameter is at Nikiski, but it also has a wide 95% confidence interval due to its short period of record.

The high water shape parameters for the Pacific Islands and Bermuda in Figure 4 vary from negative values for islands which haven't had any large storm surges, to near zero for islands which have had only a few large storm surges. Only Wake Island has a statistically significant positive shape factor, because of a greater number of hurricane strikes. At the Gulf Coast and Caribbean stations, shape parameters are positive with 95% confidence intervals which don't include zero, due to their high frequency of hurricane strikes. Two stations, Apalachicola (8726890) and Panama City (8729108) that were initially included in the analysis, however, had very large shape factors with wide 95% confidence intervals (0.60 +/- 0.29 at Apalachicola and 0.78 +/- 0.43 at Panama City). This resulted in exceedance probability curves rising so steeply that their 1% exceedance probability levels were far above those of the neighboring stations of Cedar Key and Pensacola, which have much longer periods of record. It seems that the iterative maximum likelihood estimate of the GEV parameters at those two stations may have converged to an incorrect solution. This is probably due to more frequent hurricane landfalls on this section of the gulf coast over the past 35-45 years compared to the early and mid-20th century.

In contrast to the high water shape parameters, which are regionally variable and depend greatly on the probability of hurricanes and large winter storm surges, low water shape parameters (Figures 5 to 7) are mostly negative implying a comparatively smaller likelihood of an extremely low water level far below the usual monthly or annual lowest water levels. A number of East Coast low water shape parameters are close to zero with the 95% confidence intervals including zero due to a slightly increased likelihood of an extremely negative storm surge than on the other U.S. coasts or islands. The positive value at Port Jefferson has very wide 95% confidence intervals and may be due to an inadequately short period of record.

B. GEV Stick Diagrams

The exceedance probability levels for return periods of 1.01, 2, 10, and 100 years in the plots of the annual exceedance probability curves in Appendix I and II (which are listed in Tables C and D in Appendix III), are shown for inter-station and regional comparison in Figures 8 to 13. These levels above MHHW and below MLLW are independent of time, and follow the mean sea level trend, or, in four cases, follow the mean high and low water trends for the stations which have had increasing tidal ranges.

Another way of visualizing the exceedance probability levels for each station is to expand the traditional CO-OPS stick diagrams which are used to show the levels of the tidal datums relative to each other, to the station's bench marks, and to a national geodetic datum, if there is a good leveling connection from the national network to a station's bench mark network. In Appendix III, a set of stick diagrams show the high and low 1%, 10%, 50%, and 99% exceedance probability levels, and the tidal datums of MHHW, MHW, MLW, and MLLW relative to MSL for each station. The position of the North American Vertical Datum of 1988 (NAVD88) relative to MSL is also shown, if it is available.

The relationships between tidal datums and between the tidal datums and NAVD88 are defined for the 19-year NTDE (1983-2001), or for a 5-year MTDE for the stations with high rates of change in Louisiana, Texas, and Alaska. Therefore, the stick diagrams in Appendix III, can be considered as the representative of a particular time, i.e., the mid-year of the tidal datum epoch used for the datums (1992 for most stations, or either 1999 or 2004 for the stations on a 5-year MTDE). If one wanted to project the stick diagram levels forward or backward in time relative to the MSL datum (for example, to the present year), one would use the mean sea level trend (or the mean high and low water trends, as the case may be) to calculate the amount to raise or lower the exceedance probability levels to obtain future or past positions.

C. Comparison of 1% Annual Exceedance Probability Levels between Stations

The high water 1% exceedance probability level, or the level that is expected to be exceeded once in 100 years on average, is a level often considered as a minimum height below which there is an unacceptable risk of inundation for man-made structures. This is incorporated into FEMA's approach to flood insurance practices (Crowell et al., 2007). Coastal flood insurance studies (FIS) define a set of stillwater elevations (SWELs) for coastal regions as the water level that has a 1% annual chance of exceedance. This water level is defined to exclude waves, and wave effects such as set-up and run-up. The wave heights and wave effects are then modeled to a much finer spatial scale and added to the SWELs to obtain base flood elevations (BFEs), which are the basis for the zoning on FEMA's flood insurance rate maps. The high water 1% exceedance probability levels derived in this report should roughly correspond to SWELs at locations with limited exposure to ocean waves.

The 1% GEV exceedance probability levels are shown for regional and inter-station comparisons in Figures 14 to 19 along with their 95% confidence intervals. The confidence intervals were calculated with the profile-likelihood method which allows for asymmetric confidence intervals since extreme value data places tighter restrictions on the lower bounds than on the upper bounds. This asymmetry is especially obvious on the confidence intervals of GEV curves with positive shape factors (Frechet distributions).

For the East Coast high water levels (Figure 14), Washington has the highest 1% exceedance probability level and the widest confidence interval due to several occurrences of large river floods in its record. Providence, at the north end of Naragansett Bay, and Kings Point/Willets Point, at the west end of Long Island Sound, also have very high 1% exceedance probability levels based on the extreme storm surges caused by hurricanes in 1938 and 1954. A few stations, such as Nantucket Island, Bridgeport, Solomons Island, and Mayport, have lower 1% exceedance probability levels than their neighbors, which could be either due to the period of record missing an extreme event or due to their specific geographical locations.

On the West Coast (Figure 15), high water 1% exceedance probability levels have much tighter 95% confidence intervals than on the East Coast due to the absence of hurricane strikes and because the narrowness of the continental shelf limits the wind-driven component of surge heights produced by winter storms. The levels are low from San Diego to Friday Harbor except at the Toke Point station. Toke Point is in Willapa Bay in Washington and the bay's entrance is very shallow without a dredged channel. Therefore, breaking waves at the entrance during large storm events may induce a substantial wave set-up effect causing higher water levels in the bay than on the open coast. In Alaska, the 1% levels are highest at Ketchikan, Juneau, Skagway, and the Cook Inlet stations of Seldovia, Nikiski, and Anchorage which have the greatest tidal ranges. The 1% levels are low at Unalaska and Adak Island in the Aleutian Islands.

The high water 1% exceedance levels at the island stations (Figure 16) are generally low because they are surrounded by deep water which limits the wind-driven component of storm surges. Along the Gulf Coast however, extremely large storm surges occur as hurricane-force winds interact with the wide shallow continental shelf waters. The 1% exceedance levels are highest at Galveston Pier 21 and Galveston Pleasure Pier with wide 95% confidence intervals.

The low water 1% exceedance probability levels (Figures 17 to 19) also vary greatly depending on station location. The river stations of Philadelphia and Washington show the lowest 1% levels. Port Jefferson has a large 95% confidence interval probably due to an inadequately short period of record. Nantucket Island, which is located mid-way between the coast and the continental slope, and the river station of Wilmington have lesser low water extremes. The Alaska stations with large tidal ranges such as Ketchikan, Juneau, Skagway, Seldovia, Nikiski, and Anchorage have much lower 1% exceedance probability levels than those for the rest of the west coast. The river station of Astoria has lesser low water extremes than its neighboring stations on the open coast. The Gulf Coast stations have lower 1% exceedance probability levels than the island stations with the lowest values along the northeastern part of the Texas coastline.

D. GEV Data and Trend Plots

The exceedance probability levels shown in Figures 8 to 13 were derived from the detrended annual extreme values relative to MHHW and MLLW. The original observed monthly highest and lowest data can now be displayed with the calculated exceedance probability levels superimposed, if the exceedance levels are adjusted for their time dependence, i.e., rising or falling with MHHW or MLLW. MHHW and MLLW will follow mean sea level trend, except at the four stations previously mentioned which have differing high and low trends because of their increasing tidal range. The effect of the trend on the exceedance probability levels is obtained by adjusting the levels according to the amount of time before or after the time origin (or zero time) of the station, which is 1992.5 for the stations on the 1983-2001 NDTE, and 1999.5 or 2004.5 for the stations on a 5-year MTDE. For example, the levels at mid-2012 would be obtained by adding 20 years multiplied by the mean sea level trend to the exceedance probability levels that are on the 1983-2001 datum. These plots for all the stations are displayed in Appendix IV and V.

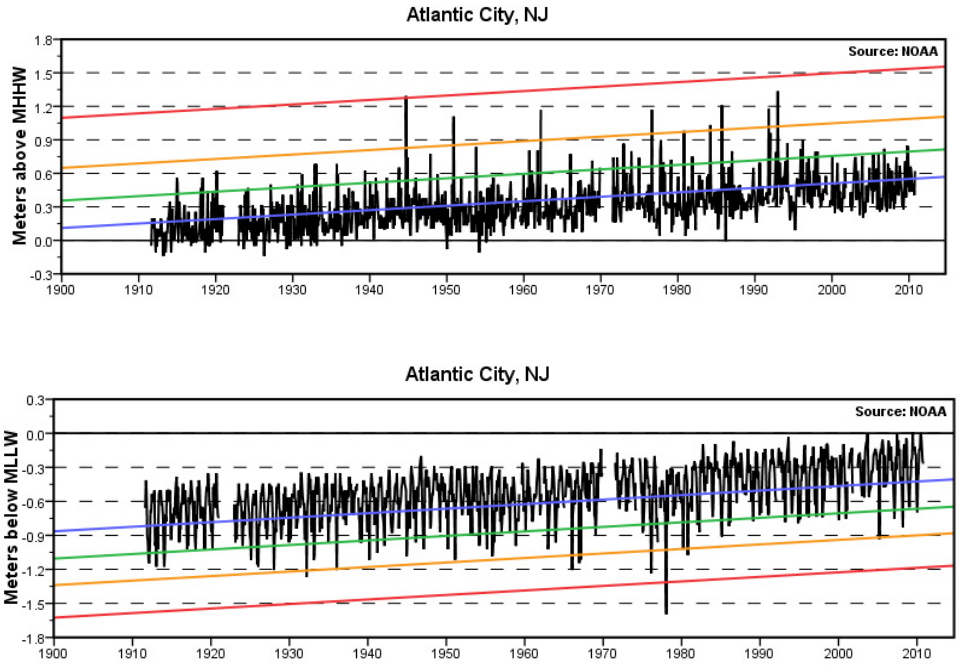

Figure 20. Monthly highest and lowest water levels for Atlantic City relative to MHHW and MLLW, respectively. Red, orange, green and blue lines are the 1%, 10%, 50%, and 99% annual exceedance probability levels. Atlantic City datums are for the 1983-2001 NDTE.

The plots in Figures 20 and 21 show examples of the monthly highest and lowest water levels and where the exceedance probability levels were at the time they occurred. This is useful in showing how a fixed level will undergo a long-term change in its exceedance probability. For stations with a positive trend like Atlantic City (Figure 20), the high water probability of exceedance at a fixed level increases over time and thus, the return period gets shorter; the low water probability of exceedance at a fixed level diminishes over time and thus, the return period

lengthens. For stations with a negative trend like Juneau (Figure 21), the high water probability of exceedance at a fixed level diminishes over time and thus, the return period lengthens; the low water probability of exceedance at a fixed level increases over time and thus, the return period gets shorter.

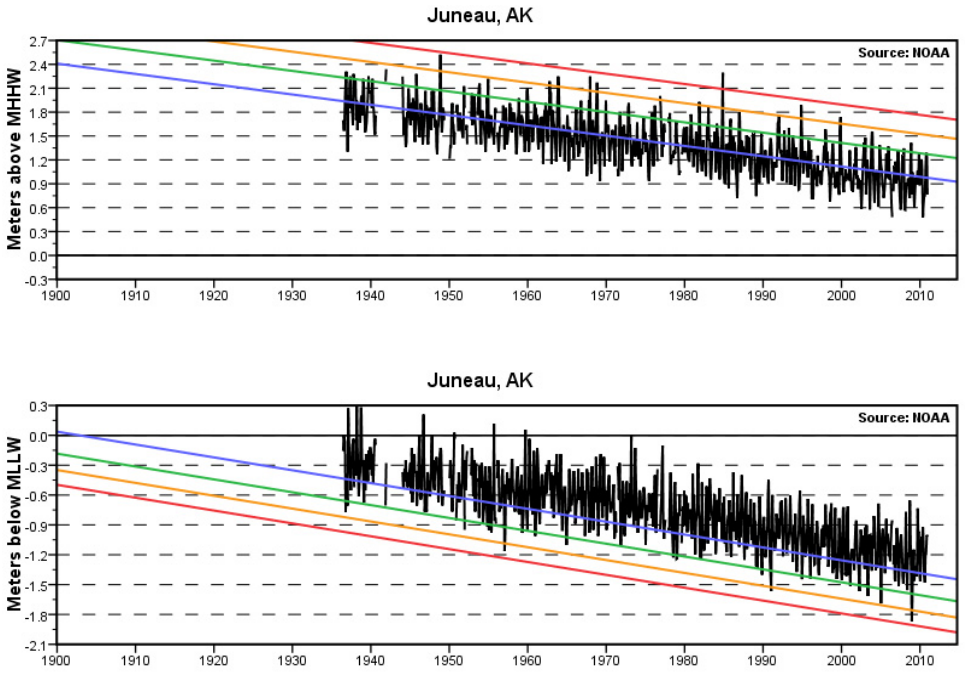

Figure 21. Monthly highest and lowest water levels for Juneau relative to MHHW and MLLW, respectively. Red, orange, green and blue lines are the 1%, 10%, 50%, and 99% annual exceedance probability levels. Juneau datums are for the modified 2002-2006 MTDE.

Therefore, in comparing two historical storm tides, it is important to consider where the exceedance probability levels were at the times that the different events occurred. For example, a storm tide today may not have exceeded today's 1% exceedance probability level, but a somewhat lower storm tide a long time ago may have exceeded the 1% exceedance probability level given its position at that time. This provides a way of evaluating the relative magnitudes of each station's extreme events independent of where mean sea level was when they occurred.

Table 5 is list of the high and low water events that exceeded the calculated 1% exceedance probability levels at each station. Due to changing mean sea levels, these events are not necessarily the highest or lowest levels ever recorded at each station. Furthermore, although these events can be considered to have an average return period of 100 years, it is possible that there is more than one such event in a station's record, even if the record is shorter than 100 years. It is also possible that there are no 100-year events in the record of a station with over 100 years of data. Many of the 100-year extreme values were caused by large-scale weather events and exceeded the 1% annual exceedance probability level at multiple stations; thus, they were probably the 100-year event for a broad coastal region.

Table 5. High and low water events which exceeded the 1% Annual Exceedance Probability Level

E. Monthly GEV Variation

The annual GEV results discussed so far give the annual likelihood of the occurrence of extreme water levels; however, these events are usually caused by some combination of meteorological and tidal forcing both of which can have a varying probability of occurrence over the course of a year. To investigate this seasonal dependence on the probability of extreme water levels, the monthly highest and lowest water level data can be divided up into twenty four subsets, one for the highest and one for the lowest water levels recorded in each individual month of the year. Then twenty four GEV analyses are carried out on the monthly extreme levels for each station. Each analysis will produce a set of location, scale, and shape parameters from which exceedance probability curves can be calculated. The 99%, 50%, 10% and 1% high and low exceedance probability levels for each month are listed in Table E in Appendix VI and Table F in Appendix VII.

Figures 20 to 25 are plots of the high and low exceedance probability levels by month for twelve stations which are representative of regional differences. For the high water exceedance probability levels (Figures 20-22), at some stations (e.g., Honolulu) there is very little seasonal dependence. At other representative stations such as Guam, Charleston, St. Petersburg, Galveston, and San Juan, where winter storms are rare and hurricanes or typhoons are common, exceedance probabilities are elevated in one or more of the summer months. At locations where winter storms are frequent and hurricanes are uncommon or nonexistent such as Boston, The Battery, San Francisco, Seattle, Sitka, and Unalaska, exceedance probabilities are more elevated in the winter months.

For the low water exceedance probability levels (Figures 23-25), there is only a small seasonal dependence at stations such as Honolulu and San Juan where they appear to follow the mean sea level seasonal cycle. At Guam, the exceedance probability levels are lowest during winter months, which are the months when extreme low water levels in the western tropical Pacific can occur during an El Niño event. At Boston, The Battery, Charleston, St. Petersburg, and Galveston the lowest extreme probability levels are also during the winter months, but are due to cold season storminess in the Atlantic and Gulf of Mexico. St. Petersburg also has a lowered 1% exceedance probability level during September, which is due to a few strong hurricanes which, having crossed southern Florida, deliver intense offshore winds to Florida's west coast. The west coast stations of San Francisco, Seattle, and Sitka have lower exceedance probability levels in summer and winter relative to the levels in March and September. This seasonality is due to a variation in tidal forcing over the course of a year which, for almost all U.S. coastal regions, gives higher amplitude spring tides during the solstices and lower amplitude spring tides during the equinoxes (Merrifield et al., 2007). There are other parts of the global ocean that have higher amplitude spring tides during the equinoxes (March and September) than during the solstices (June and December).

V. Summary and Conclusion

The goal of this investigation was to quantify the likelihood of storm tide inundation along the U.S. coastline with a focus on the least common, most extreme events. This study made use of a valuable data set consisting of the highest and lowest monthly water levels recorded at 112 long-term U.S. water level stations. Ten of the stations had over 100 years of data. Using the data up to 2010, all of the stations had over 30 years of data except for two west coast stations, where good results were obtained with 26 and 27 years of data (Rincon Island and Nikiski, respectively).

After extensive quality control checking of the data, sets of monthly highest and lowest water levels were obtained for each station. The data were then detrended using the mean sea level trends calculated with data up to 2006 (Zervas, 2009), except at four stations where separate mean high and low water trends were used for detrending, due to the stations' increasing tidal ranges over their periods of record. A set of annual highest and lowest water levels were then generated. The GEV analysis method was chosen as the appropriate statistical model for extreme data values. The extRemes package of the R statistical software environment was used to calculate the GEV parameters for each station's high and low water extreme values.

The results of the GEV analyses were presented in tables and figures to display them for discussion and for practical applications. The high and low water exceedance probability curves and their 95% confidence intervals were plotted along with the detrended annual extreme values from which they were derived. The shape parameters, which have a great influence on the behavior of the exceedance curves at longer return periods, were compared by regions to show similarities and differences between neighboring stations.

The high and low water 99%, 50%, 10%, and 1% exceedance probability levels were displayed in plots by region and were used to construct stick diagrams for each station showing the relationship of these levels to MSL, the other tidal datums, and to the NAVD88 geodetic datum, if it was available. Station-to-station comparisons were also made of the 1% GEV exceedance probability levels and their 95% confidence intervals which may be comparable to the SWELs used by FEMA in flood insurance studies as the basis for their flood insurance rate maps.

The original data were then plotted along with the calculated exceedance probability levels which rise or fall in conjunction with a station's MSL. The extreme events which exceeded the 1% exceedance probability level and which can be considered as the events with a 100-year return period, are identified in a table. Finally, a set of twenty four GEV exceedance probability analyses were carried out for each station using the high and low water values for each month of the year in order to demonstrate seasonal variability in the likelihood of the occurrence of extreme events.

The width of the 95% confidence intervals calculated for the exceedance probability curves vary greatly with the return period, the years of data available for analysis, and with the GEV shape

parameter which characterizes the distribution of the extreme values. Although at longer return periods, the confidence intervals always get wider, the stations with negative shape parameters have quite narrow confidence intervals up to and beyond the 100-year return periods. At stations with positive shape parameters, however, the confidence intervals can be very wide at the 100-year return period. The continued collection of more years of data, and the future recalculation of the GEV exceedance probability parameters should gradually narrow the widths of the confidence intervals.

The results of this investigation should have many potential uses. Knowledge of the positions of the exceedance probability levels will allow the level reached by any future storm event to be immediately put in a historical context. In conjunction with numerical operational forecast models, predicted storm tides, when accompanied with a station's exceedance probability levels, can be used to prepare for the impacts of an approaching storm system.

The exceedance probability levels will also be useful in the planning and construction of man-made infrastructure in coastal regions of the United States. The likelihood of fixed levels being inundated over the design lifetime of a structure needs to be quantified for the planning and construction of roads, bridges, buildings, ports, and drainage systems. The exceedance probability levels should also prove useful in the management and restoration of natural ecosystems such as marshlands, reefs, beaches, and barrier islands.

Exceedance levels can also be projected into the future by raising or lowering the levels according to either the historical linear trends or by taking into account non-linear future scenarios for global and/or regional sea level rise. With continually changing sea levels, the probability of exceedance at a fixed elevation will also undergo a continuous change each year.

ACKNOWLEDGMENTS

This report is a product of data gathering, quality control, research, analysis, and peer review over an extensive period of time and was therefore greatly improved by contributions from many people. Tom Huppmann's SQL queries help greatly with the extraction of data from the CO-OPS database and with keeping current with any changes made to the originally-downloaded data sets. Substantial assistance at other points of the project was provided by Carolyn Lindley, Lori Fenstermacher, Adria Schneck-Scott, and Robert Kushner. Steve Gill, Billy Sweet, John Boon, and Jeffrey Gebert reviewed the draft report and made many useful suggestions to improve the clarity of the final product. Thanks to Brenda Via who prepared this publication for printing and posting on the CO-OPS website.

Appendix I.

Annual GEV Exceedance Probability Curves for High Waters

Note: Black dots indicate the annual highest water levels shown in the Weibull plotting positions. Thicker black line is the GEV exceedance probability curve and the thinner black lines indicate the upper and lower 95% confidence intervals. The vertical red, orange, green, and blue lines are the return periods of the 1%, 10%, 50%, and 99% annual probabilities of exceedance. The zero value on the vertical axis represents the elevation of the MHHW datum for the National Tidal Datum Epoch (1983-2001) or the special 5-year Modified Tidal Datum Epoch, as appropriate.

Appendix II.

Annual GEV Exceedance Probability Curves for Low Waters

Note: Black dots indicate the annual lowest water levels shown in the Weibull plotting positions. Thicker black line is the GEV exceedance probability curve and the thinner black lines indicate the upper and lower 95% confidence intervals. The vertical red, orange, green, and blue lines are the return periods of the 1%, 10%, 50%, and 99% annual probabilities of exceedance. The zero value on the vertical axis represents the elevation of the MLLW datum for the National Tidal Datum Epoch (1983-2001) or the special 5-year Modified Tidal Datum Epoch, as appropriate.

Appendix III.

Stick Diagrams of the Annual GEV Exceedance Proabiltiy Levels Relative to Tidal and Geodetic Datums

Note: Red, orange, green, and blue symbols indicate the 1%, 10%, 50%, and 99% high and low annual GEV exceedance probability levels relative to MSL. Black symbols indicate the MHHW, MHW, MLW, and MLLW tidal datums and the geodetic datum NAVD88, if available. The zero value on the vertical axis represents the elevation of the MSL datum for the National Tidal Datum Epoch (1983-2001) or the special 5-year Modified Tidal Datum Epoch, as appropriate.

Table C. High Water Level 0.99, 0.50, 0.10, and 0.01 GEV Exceedance Probability Levels (meters above MHHW)

Appendix IV.

Time series of monthly highest water level and GEV exceedance probability levels

Note: Black line indicates the monthly highest water level. Red, orange, green and blue lines represent the 1%, 10%, 50%, and 99% annual probability of exceedance levels . The zero value on the vertical axis represents the elevation of the MHHW datum for the National Tidal Datum Epoch (1983-2001) or the special 5-year Modified Tidal Datum Epoch, as appropriate.

Appendix VIII.

Effect of Hurricanes Irene and Sandy on High Water Exceedance Probability Levels for Bridgeport, The Battery, and Sandy Hook

In late October 2012, Hurricane Sandy struck the coast of New Jersey. The storm's large area, direction of motion relative to the coastline, strong winds, and low barometric pressure caused a large storm surge along the Mid-Atlantic coast from Cape Cod to Cape Hatteras. At most long-term NWLON stations, the peak water levels were high, but not the historically highest levels, with the exception of two stations in New York Harbor (The Battery and Sandy Hook) and at Bridgeport on Long Island Sound.

At Bridgeport, the level reached by Sandy was 0.304 meters above the previous historic record, from a December 1992 winter storm. At The Battery, Sandy reached a level of 1.228 meters above the previous record from Hurricane Donna in 1960. At Sandy Hook, the gauge stopped recording at 23:36 on October 29, after reaching a level of 0.959 meters above the previous historic record, also from Donna in 1960. Because these new maxima are so far above the previous maxima, they cause a significant change in the shapes of any calculated exceedance probability curves especially at the longer return periods. Therefore, in this Appendix, the high water GEV parameters for these three stations are recalculated with the inclusion of the highest levels for 2011 and 2012, which were the peak levels reached by Hurricane Irene and Hurricane Sandy at all three stations.

Since the Sandy Hook station malfunctioned before reaching its peak during Hurricane Sandy, a couple of nearby high water marks (HWMs) leveled by the USGS to the NAVD88 geodetic datum were considered. The marks are about 0.5 kilometers north and south of the station and reached levels of 11.57 and 11.06 feet above NAVD88, respectively (McCallum et al., 2013). The average of the two HWMs is equivalent to 3.449 meters above NAVD88 which is 2.714 meters above MHHW. This peak level at Sandy Hook is 0.274 meters above the last recorded level received from the gauge before it was destroyed and, therefore, is 1.233 meters above the level reached by Hurricane Donna in 1960.

In Table G, the location, scale, and shape parameters of the high water level GEV solutions are shown as a comparison between the results with and without the 2011 and 2012 maxima. The locations parameters are negligibly higher and the scale parameters are slightly higher with the additional two years. The most significant change is the increase in the shape parameters which indicate how steeply the exceedance probability levels rise as the return period lengthens. At The Battery and Sandy Hook, the shape parameters become more positive and at Bridgeport the shape parameter changes from a negative value (Weibull distribution) to a positive value (Fréchet distribution).

Table G. Comparison of High Water Level GEV Location, Scale, and Shape Parameters							
Station Number	Station Name	Location Parameter (meters)	+/- 95% Confidence Interval	Scale Parameter (meters)	+/- 95% Confidence Interval	Shape Parameter	+/- 95% Confidence Interval
Through 2010							
8467150	Bridgeport	0.704	0.052	0.160	0.037	-0.037	0.198
8518750	The Battery	0.676	0.030	0.149	0.022	0.058	0.124
8531680	Sandy Hook	0.706	0.039	0.157	0.030	0.142	0.175
Through 2012 (including Irene and Sandy)							
8467150	Bridgeport	0.709	0.055	0.172	0.040	0.072	0.201
8518750	The Battery	0.676	0.031	0.155	0.023	0.142	0.117
8531680	Sandy Hook	0.709	0.041	0.167	0.033	0.226	0.173

Table H is a comparison of the 0.99, 0.50, 0.10 and 0.01 GEV exceedance probability levels for the three stations with and without the high water maxima for 2011 and 2012. The exceedance probability curves are also plotted versus return period in Figures 28, 29, and 30 for the three stations. The shorter return period sections of the curves (0.99 and 0.50 exceedance probabilities) are negligibly higher with the two additional years. The 0.10 exceedance probability levels are slightly higher and the 0.01 exceedance probability levels are substantially higher, primarily due the level reached by Hurricane Sandy, which steepens the curves and widens the confidence intervals at the longer return periods.

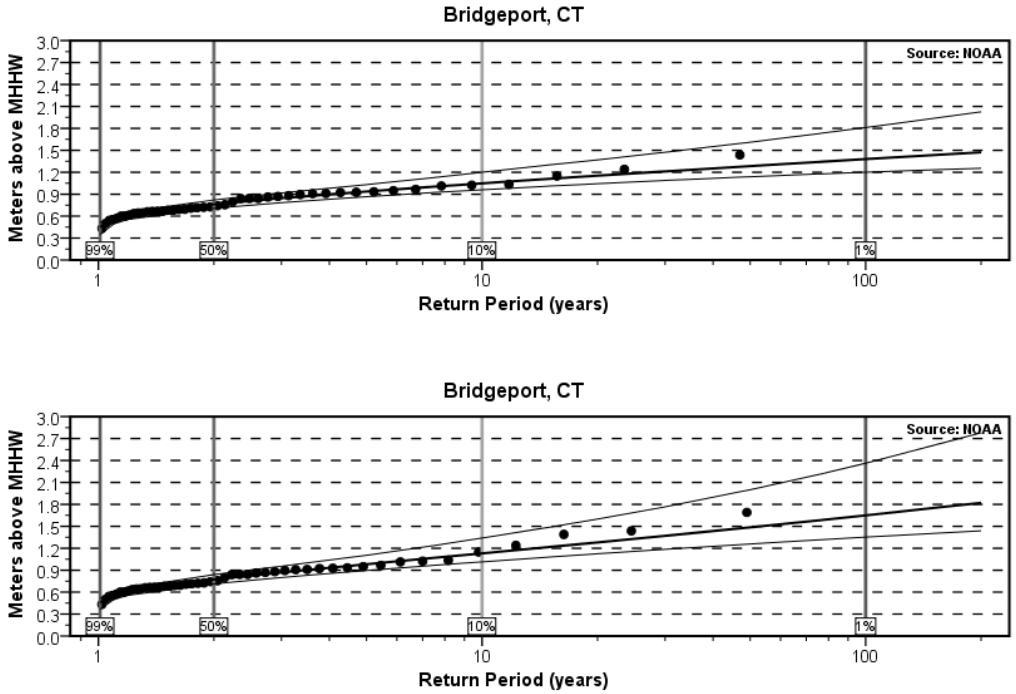

Figure 28. High water GEV exceedance probability curves with 95% confidence intervals at Bridgeport before (top) and after (bottom) inclusion of the 2011 and 2012 maxima.

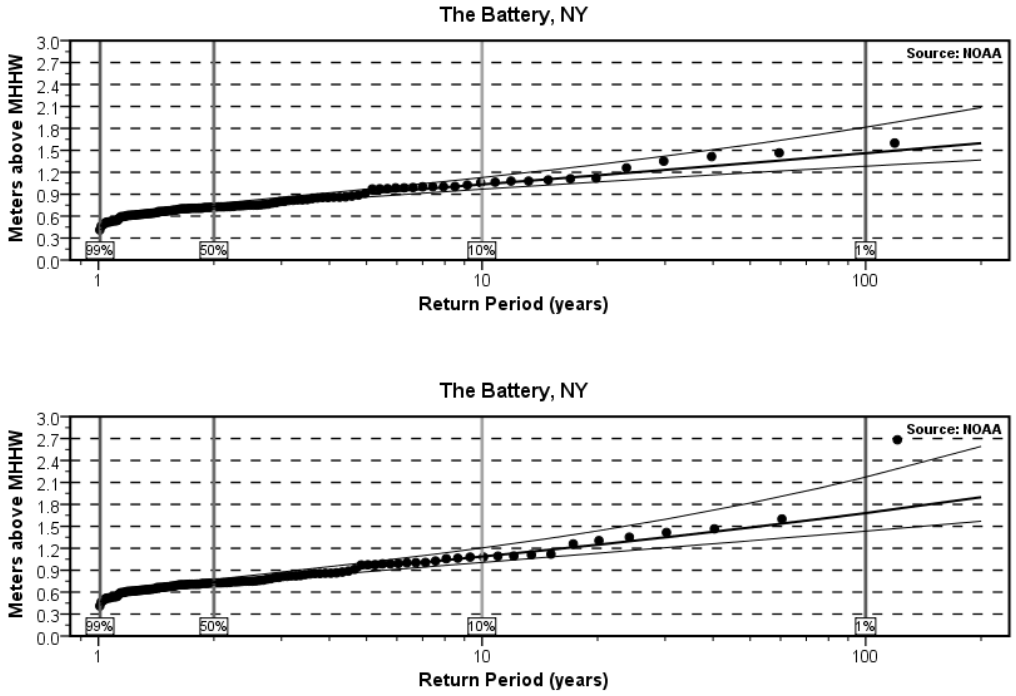

Figure 29. High water GEV exceedance probability curves with 95% confidence intervals at The Battery before (top) and after (bottom) inclusion of the 2011 and 2012 maxima.

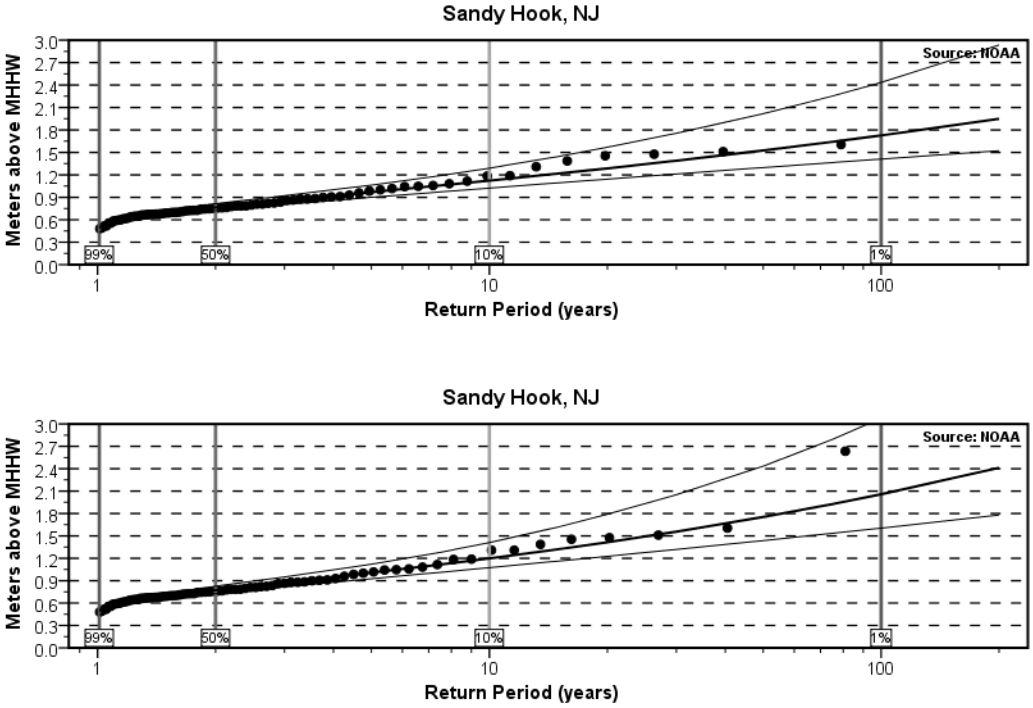

Figure 30. High water GEV exceedance probability curves with 95% confidence intervals at Sandy Hook before (top) and after (bottom) inclusion of the 2011 and 2012 maxima.

The station stick diagrams were discussed in Section IV.B and plotted in Appendix III showing the positions of the 99%, 50%, 10% and 1% annual GEV exceedance probability levels relative to MSL and the tidal datums. The effect of the recalculation of the high water exceedance probability levels for Bridgeport, The Battery, and Sandy Hook are displayed in Figures 31, 32, 33, showing the increased high levels obtained by including the peaks from Hurricane Irene in 2011 and Hurricane Sandy in 2012.

A consequence of the recalculation of the high water GEV curves for these three stations is that Hurricane Sandy now becomes the only historically recorded event exceeding the 1% annual exceedance probability level at all three stations. In Table 5 in Section IV.D, the level reached by the winter storm on 12/11/1992 at Bridgeport no longer exceeds the 1% annual exceedance probability level. At The Battery, the winter storm on 11/7/1953 and Hurricane Donna on 9/12/1960 also no longer exceed the 1% annual exceedance probability level.
