

HEAT INDEX CLIMATOLOGY FOR THE NORTH-CENTRAL UNITED STATES

Todd Rieck
National Weather Service
La Crosse, Wisconsin

1. Introduction

Heat is an underrated danger, with an average of 175 Americans losing their lives annually from heat-related causes. According to the Centers for Disease Control and Prevention, from 1979-2003 excessive heat exposure caused 8,015 deaths in the United States. During this period, more people died from extreme heat than from hurricanes, lightning, tornadoes, and floods combined.

Heat kills by taxing the human body beyond its ability to cool itself. Cooling is primarily accomplished by the evaporation of perspiration. How efficiently this process functions is directly related to the amount of water vapor in the air. High moisture content reduces the evaporative cooling rate of perspiration, making it difficult for the body to maintain a steady and safe internal temperature. One way to measure the combined effect of temperature and moisture on the human body is the heat index.

In 1979, R. G. Steadman constructed an apparent temperature table using temperature, relative humidity, and other factors, based on a number of published research papers over a 54-year span. The National Weather Service (NWS) developed a heat index equation based on Steadman's work as guidance for heat-related advisories or warnings. Heat advisories or warnings are issued to the public when values approach dangerous levels.

This study will attempt to show the frequency of various heat index values for a section of the United States, focusing on the Plains, upper and

middle Mississippi River Valleys, and the western Great Lakes. Also, the physiological response to heat will be briefly investigated, including a review of how heat acclimatization affects the human body's biology. This protective biological response is an important consideration when evaluating the impact of the heat on those that are, or are not, acclimatized to the heat.

In this study, 95°F will be used as the start for the climatological analysis as prolonged exposure to heat this warm increases the risk of sunstroke, heat cramps, and heat exhaustion (Table 1) .

2. Data

All available weather observations from the National Climatic Data Center were used from 192 locations (Fig. 1), extending from Utah to Michigan, and from the Canadian-U.S. border south to a northern New Mexico to Arkansas line. Initially, the period of record used was the last set of climate normals, 1971-2000. Due to some data unreliability and station closures, a majority of the sites only had data extending back to 1973. This study focused on the summer months of June, July and August, when the combination of heat and humidity produces the highest heat indices. Some areas of study were under-represented by the original data set. In an attempt to fill these data voids, "newer" locations were used and therefore more recent data (1990 to the present) were incorporated into the data set. These additional data were used sparingly, trying to keep the data set as true to the 1971-2000 period as possible.

Central Plains are a favored location for warm to hot summer temperatures and high heat indices are expected. Meanwhile, the middle Mississippi River Valley is generally not as warm as locations to the west, but dew points during the summer are high. This is largely the result of two processes: moisture from the Gulf of Mexico transported north, and evapotranspiration from vegetative cover. Looking more closely at this broad area, the influence of the Ozarks is noted with a relative minimum of high heat indices in this area (Figs. 4-5).

A few other, more minor maxima are evident, especially on the 100°F or greater heat index map (Fig. 4). Over central South Dakota, a maximum is indicated near Pierre and areas to the east. While there are not many data points in this area, this maximum appears to be valid for a couple reasons: geography and irrigation. In South Dakota the terrain transitions from a hilly, drier, and more arid land in the west (Black Hills and the Badlands), to flatter terrain, more vegetation and crops in the east. The higher percentage of crops and vegetation requires more irrigation resulting in additional evaporation and evapotranspiration.

Another minor maximum is located over southwest Minnesota. This area is located on the lee side of the Buffalo Ridge, which is a large expanse of rolling hills and the second highest point in Minnesota. Down sloping winds off this ridge can lead to warmer temperatures compared to surrounding portions of Minnesota. In addition, agriculture is predominant across southern Minnesota, adding moisture via evapotranspiration. These influences likely play a role in the higher heat indices.

A minimum in the heat index is indicated over southeast Minnesota (Figs. 3-4). Rochester is the data point associated with these lower values, and this observation site is located at the airport, on an open and unsheltered ridge south of the city. Its location makes it cooler than surrounding areas, with lower dew points. Therefore, while representative for the data point

itself, the localized minimum is not as widespread as the figures would suggest.

One more maximum of note is located over southeast Colorado, and is only apparent on the 95°F air temperature and heat index maps (Figs. 2-3). A likely explanation for this would be deep mixing in the afternoon leading to warm temperatures but low humidities. Further investigation of the data points responsible for this maximum (PUB, LAA, and LHX) revealed that all the instances of 95-degree temperatures or heat indices occurred late in the afternoon, during peak heating. Relative humidities were less than 30% in nearly all cases with temperatures above 100°F about 60% of the time. This supports the maximum indicated in Figures 2 and 3. However, at temperatures this warm, further moisture would be required to raise the heat indices higher. In a deeply mixed environment, this is difficult to accomplish without some form of moisture advection. Since this is rare on days this warm over southeast Colorado, a maximum is not evident for heat indices above 95°F (Figs. 4-6).

In the more northern latitudes, temperatures are generally not as warm, nor is there a nearby large source of moisture (i.e., Gulf of Mexico). Therefore, the frequency of high heat indices is much less.

4. Physiological Effects of Heat

The body tries to maintain a consistent temperature by using various means to cool or warm itself. When blood is heated above 98.6°F, the body attempts to dissipate this extra heat by losing water through the skin and sweat glands, varying the rate and depth of blood circulation, and as a last resort – panting. About 90 percent of the body's heat is lost through the skin, mostly through perspiration. Above 98.6°F, heat can only be lost through sweating.

Sweating itself does not cool the body; rather, it's the evaporation of this water that performs this function. Energy is required to change liquid water into a vapor, and the body provides this in the form of heat. However, some water vapor condenses back onto the body, returning some of that heat energy back to the body. In order for the body to cool, the rate of evaporation needs to exceed the rate of condensation. As the humidity increases, the rate of condensation starts to limit the amount of cooling from evaporation, causing the core body temperature to rise. In addition to overheating, the loss of water through sweating can lead to dehydration and can cause chemical imbalances in the body as essential minerals (such as salt) are lost through the sweat. Dehydration also depletes the body of water needed for sweating and thickens the blood. The heart has to pump harder to move the blood through the body, straining the heart and blood vessels as it does. The increased heart rate and blood flow can cause harm, or even death, to those with heart

or circulatory diseases.

Overall, the inability of the body to shed heat, and the loss of fluids and minerals through sweating, can result in various heat-related disorders and illnesses, such as heat cramps, heat exhaustion, and heat stroke (Table 1). One common element to them all is that the individual affected has either overexposed or overexerted him or herself in a very warm (and likely humid) environment. Research has also shown that the severity of heat disorders increases with age. For instance, what may cause heat cramps in a 17-year old could result in heat exhaustion in someone 40, while a 60-year old could suffer heat stroke.

Heat Acclimatization

Heat acclimatization is a term used to describe the physiological adaptations associated with prolonged exposure to high environmental temperatures. During the process, resting pulse rate decreases, blood flow to the skin improves, and sweating increases. Sweat becomes more watery so that heat loss from the body can be maximized without losing too much salt. Heat-acclimatized individuals suffer less from nausea, dizziness, and discomfort in hot conditions.

The bulk of the available research focuses on short-term acclimatization: how quickly individuals laboring or performing strenuous athletics in high heat environments can adjust to the heat. Acclimatization takes about 1 to 2 weeks, but when removed from this environment, can be lost in nearly the same amount of the time. Resting in the heat results in some acclimatization, but a greater adaptive state can be induced by intermittent exposure to exercise in the heat (Greenleaf and Kaciuba-Uschiko 1989). A degree of acclimatization can also be achieved by just living and working in a hot climate. However, those that participate in strenuous outdoor activities usually acclimatize more rapidly, and retain the benefits longer, compared to sedentary individuals.

Heat Index	Possible heat disorders for people in higher risk groups
130°F or higher	Heatstroke/sunstroke highly likely with continued exposure.
105-130°F	Sunstroke, heat cramps or heat exhaustion likely, and heat stroke possible with prolonged exposure and/or physical activity.
90-105°F	Sunstroke, heat cramps and heat exhaustion possible with prolonged exposure and/or physical activity.
80-90°F	Fatigue possible with prolonged exposure and/or physical activity.

Table 1. Heat indices and the heat-related disorders possible within each range (source: <http://www.weather.gov/om/brochures/heatwave.pdf>).

This research supports the perception that individuals that are more accustomed to the heat (i.e., live in a warmer climate) will have a higher tolerance and be less affected by it, compared to individuals that live in cooler climates. However, the research also suggests that full acclimatization occurs by coupling active outdoor activities (sports, labor, etc.) with a very warm environment.

Heat acclimatization acts to protect the body from the heat. When discussing the impacts of high temperatures and humidity, this biological response should be taken into consideration.

5. Summary

Heat is an underrated danger, and the heat index is a way to assess the threat from the combined effects of the air temperature and humidity. Around 175 people in the United States lose their lives each year from heat related causes.

A review of historical summer (June through August) observations for 192 locations, mostly across the Plains and upper and mid-Mississippi River Valleys showed a propensity for dangerous heat across the Central Plains into the mid-Mississippi River Valley. The geographic and climatic location, along with proximity to the Gulf of Mexico, makes these areas prone to very warm temperatures, and in some cases, high humidity. This results in more frequent and higher heat indices. Other more localized maxima are located over portions of central South Dakota, and southwest Minnesota. Across the bulk of the Northern Plains and Great Lakes States, frequencies of high heat indices are much lower due to the latitude and geographical location.

Research has shown that active individuals in warm environments can become acclimatized to the heat. The body adjusts to these high heat conditions, helping to protect itself from the heat's effects. Comparatively, sedentary individuals in a similar environment do not acclimatize as well and will be at a higher risk to

suffer from heat-related illnesses. Individuals unaccustomed to very warm environments, such as those that live in higher latitudes, will also be at a greater risk as their bodies have had little exposure, and therefore time, to acclimatize.
